Data from Hodkinson, I.D. (2013). Terrestrial and freshwater invertebrates. In: Mølltofte, H. (ed.), *Arctic Biodiversity Assessment. Status and Trends in Arctic biodiversity*, pp. 194–223. Akureyri: Conservation of Arctic Flora and Fauna; Makarova, O. L., Sviridov, A. V., and Klepikov, M. (2013). Lepidoptera (Insecta) of polar deserts. *Entomological Review* **93**, 225–239; Chernov, Y. I., Makarova, O. L., Penev, L. D., and Khruleva, O. A. (2014). Beetles (Insecta, Coleoptera) in the Arctic fauna: Communication 1, faunal composition. *Entomological Review* **94**, 438–478.

As elsewhere in the Arctic, Diptera comprise the most important insect order on Svalbard. As discussed above, Diptera are better adapted to the cold, harsh Arctic climate than any other order of insects. They form the dominant order in all regional Arctic insect faunas, in terms of both abundance and diversity. A total of 136 species are known from this archipelago, dominated by more than 66 species of midges (Chironomidae).

As with the Coleoptera, Svalbard has surprisingly few wasps (Hymenoptera). Coulson et al. (2014) list 39 species of Hymenoptera from this archipelago. The majority of these are parasitic wasps in the families Ichneumonidae (22 species) and Braconidae (5 species). There are also seven species of sawflies (Tenthredinidae). The braconid wasps from Svalbard parasitize the two endemic aphid species. The Hymenoptera fauna of Greenland includes 203 known species, more than 5 times the number of species on Svalbard. The disparity in the diversity of Coleoptera and Hymenoptera between Svalbard and Greenland must be due, in part, to the differences in the area of ice-free land between the two Arctic island groups, but it would seem that the serendipity of post-glacial colonization must have also played a role in these differences.

The Lepidoptera fauna of Svalbard is extremely depauperate. The resident species total just three, the diamondback moth *Plutella polaris*, the snout moth *Pyla fusca*, and the owlet moth, *Apamea exilis*. *P. polaris* is apparently endemic to Svalbard. Another *Plutella*, *P. xylostella* (Fig. 5), is occasionally collected on Svalbard, but is too warm-adapted to overwinter there. Again for comparison, Greenland has 51 known resident species of Lepidoptera, representing 15 families of moths and butterflies. Svalbard has one species of caddisfly: *Apatania zonella* (Fig. 5). The larvae are active throughout the summer, using their mouthparts to scrape food (detritus or algae) from rocks in streams.

The Svalbard insect fauna is made up of Holarctic and Palearctic species. It would appear that the archipelago was colonized almost exclusively from northwestern Eurasia after the last ice age. The distances from North America are too great, and the ocean currents and winds flow in the wrong directions to facilitate North American insect dispersal to Svalbard.

Coulson (2007) noted that more than 80% of insect faunal surveys on Svalbard come from just three locations along the west coast. This introduces a bias in our knowledge of the invertebrate fauna, because the west coast has a relatively mild climate due to the influence of the North Atlantic Drift. There has been little study of the ice-free regions of the east coast of Svalbard, but these regions likely have a different insect fauna, for two reasons. First, the predominant winds and oceans currents originating from the north east create considerably colder conditions here. Second, because of the influences of different winds and currents, this coast will have experienced a different colonization history.

Franz Josef Land and Novaya Zemlya

Franz Josef Land lies north-east of Svalbard between $79^{\circ}73'$ and $81^{\circ}93'N$ and 37° and $65^{\circ}50'E$. It comprises ~ 191 uninhabited islands with a total land area of $12,334 \text{ km}^2$ (Fig. 10). Cape Fligely, on the north coast of Prince Rudolf Island ($81^{\circ}50' N$), is the northernmost point in Eurasia and the Eastern Hemisphere. About 85% of the island landscapes are covered with glacial ice, leaving only about 1850 km^2 of ice-free land. This area is about 14% of the ice-free area of Svalbard. The mean July temperature is 2.1°C . The mean January temperature is -22.7°C . Mean annual precipitation is 259 mm. The islands are surrounded by sea ice from about September to June. Skies are cloudy about 90% of the time, reducing solar heating at ground level.

Franz Josef Land was a closed military area for much of the 20th century and even today access requires permission from the Russian government, including the Federal Service of National Security and the Administration of Reserves and Protected Areas. Little work has been done on the insect fauna of these High Arctic islands.

Novaya Zemlya consists of two main islands and some smaller adjacent islands. The islands lie north of the Nenetsia Russian coast. The two principle islands, Severny to the north and Yuzhny to the south, are separated by the Matochkin Shar strait. The island group is situated between 70° to $77^{\circ}N$ and 51° to $69^{\circ}E$ (Fig. 11). The main islands stretch almost 900 km along a north-east to southwest trending arc that is up to 145 km wide. Novaya Zemlya has an area of $81,280 \text{ km}^2$ of which 27% is currently glaciated, leaving over $59,000 \text{ km}^2$ of ice-free landscapes, more than twice the ice-free area of Svalbard. Mean July temperature at the Malye Karmakuly meteorological station ($72^{\circ}22'N$, $52^{\circ}42'E$) on southwest Yuzhny Island is 7.3°C . Mean January temperature is -14.1°C . Mean annual precipitation is 336 mm. As with Svalbard, the climate of Novaya Zemlya is heavily influenced by the surrounding ocean waters. The west coast is warmed by warm North Atlantic waters, while east coast is chilled by the cold waters of the Kara Sea. This coast is ice-bound during winter.

Fig. 10 Map of Franz Josef Land.

Fig. 11 Map of Novaya Zemlya.

During the Cold War, parts of both main islands of Novaya Zemlya were used as nuclear test sites. Since 1954, 224 nuclear detonations have been carried out on Novaya Zemlya. The islands remain a closed military region and thus difficult for biologists to visit.

Because of its extreme northern position and predominance of ice-covered landscapes, the islands that make up Franz Josef Land have only 13 recorded species of insects ([Table 6](#)). It could well be that many more species would be found if more extensive entomological field investigations were carried out there, but the extremely cold temperatures and lack of biological productivity of these Polar Desert islands precludes great diversity of insect species there. Vascular plant cover here is restricted to less than 15% of the landscape.

The Franz Josef Land fauna includes five species of chironomids, one dark-winged fungus gnat (Sciaridae) and seven species of moths. No wasps or beetles have been found there. No lice or fleas have been found. The Novaya Zemlya insect fauna is far more abundant and diverse, as might be expected. More than 167 insect species have been identified from these islands ([Table 6](#)). These include 7 species of lice, one aphid, 11 species of beetles, more than 73 species of chironomids and more than 75 species from other Diptera families, 20 species of ichneumon wasps, 4 species of braconids, and 3 species of bumblebees. There are 14 resident species of Lepidoptera known from Novaya Zemlya. The fauna contains mainly species with circumpolar Arctic distributions.

Given that the three archipelagos are in relatively close proximity to each other ([Fig. 12](#)), it is somewhat surprising that they share very few insect species in common. As shown in [Table 7](#), the greatest number of species in common (35) are shared between Svalbard and Novaya Zemlya. Franz Josef Land has only one species of moth in common with Svalbard, and no species in common with Novaya Zemlya. Apparently there has been very limited connectivity between these island groups. We clearly need a better understanding of the relative importance of eastern and western sources of colonization over time in order to unravel this anomaly.

[Coulson et al. \(2014\)](#) commented on the small number of endemic species, both on the individual archipelagos and for the region as a whole. There are several possible explanations for this phenomenon. One may be the lack of extensive insect collecting, especially on Novaya Zemlya and Franz Josef Land. Or the paucity of endemism may reflect the young age of the communities, having become established only during the Holocene. On the other hand, the insect fauna of Greenland includes 34 endemic

Data from Coulson, S.J., Convey, P., Aakra, K., Aarvik, L., Ávila-Jiménez, M.L., et al. (2014). The terrestrial and freshwater invertebrate biodiversity of the archipelagoes of the Barents Sea: Svalbard, Franz Josef Land and Novaya Zemlya. *Soil Biology & Biochemistry* **68**, 440–470.

species representing 10 families scattered in 5 orders of insects. Greenland was likewise fully glaciated during the Late Pleistocene, so its fauna had no more time to evolve new species than the Barents Sea archipelagos.

The Beringian Refuge

Beringia is an ancient arctic landscape that no longer exists as an intact body of land. During Late Pleistocene glaciations when global sea level was lowered by 60 m or more, the shallow continental shelf regions between northeastern Siberia and western Alaska became dry land, forming a land bridge between the two continents. The Bering Land Bridge was not a narrow isthmus between Siberia and Alaska. Rather, it was a more-or-less hourglass-shaped landscape that was twice the size of the state of Texas. This land bridge not only allowed the passage of many species of plants and animals between the two continents, it was essentially the *only* land connection between the Old World (the Palearctic region) and the New World (the Nearctic). That this land bridge remained unglaciated throughout the Pleistocene is quite remarkable, since the vast majority of Arctic landscapes were covered with glacial ice during each glacial interval, and the glaciations span as much as 90% of the last 2.5 million years.

Beringia has long been the focus of biogeographic research. There are two principal reasons for this. First is the connection between Asia and North America provided by the Bering Land Bridge. Second, it has been established that Beringia played a key role as a refuge for Arctic biota during repeated episodes of Pleistocene glaciation. Not only the Bering Land Bridge, but also the vast lowland regions of northeastern Siberia, interior Alaska, and the Yukon Territory of Canada remained essentially ice-free,

even during times of maximum glaciation. As discussed above, such an Arctic refuge was not available to the flora and fauna of Greenland or the Barents Sea archipelagos.

Thus the region we call Beringia provided critical habitats for the cold-adapted biota of the Arctic, and it also provided a terrestrial pathway linking the two major continents of the Northern Hemisphere. The Holarctic modern distributions of many mammalian species led biogeographers as far back as Wallace (1876) to speculate on an ancient connection between Siberia and Alaska. More substantial evidence for the Bering Land Bridge was provided by botanist Erik Hultén in 1937, based largely on his studies of the modern floras of Alaska and Siberia. Beginning with Hopkins (1967) and continuing with Hopkins (1982) and Hoffecker and Elias (2007), research on Beringian paleoenvironments has been well summarized.

Arctic Insects and Climate Change

Arctic insects have survived the waxing and waning of polar ice sheets and glaciers since time immemorial. The fossil record indicates that many species have persisted throughout the Pleistocene, the last 2.6 million years. The record holder for longevity of an arctic species is the water scavenger beetle, *Helophorus arcticus* (Fig. 4). Fossils of this species have been found in Siberian deposits dating back ~20 million years (Fikáček et al., 2011). Arctic insects have survived not by evolving new adaptations, but by shifting their distributions in response to climate change. Cold intervals saw the distributions of Arctic insects shift either southwards, or into the Beringian refuge. Warm intervals saw their expansion into recently deglaciated landscapes. This natural process has repeated itself dozens of times since Quaternary glaciations began. The fossil record demonstrates that each major climatic change brings about a new reshuffling of species into specific regions. However, Arctic insects are extremely vulnerable to the current global warming, which is amplified at the poles. This is because the pace and amplitude of the current and predicted future changes greatly exceed those of previous warming intervals. As temperatures rise, especially in the Arctic, the native fauna will suffer and decline. Insects living in the High Arctic can find no more northerly places available for immigration. The rising temperatures will decrease the fitness of cold-hardy insects, and they will also be forced to compete with more warm-adapted insects, invading from the south. Likewise, changes in the composition of high latitude plant communities, a phenomenon already documented in many Arctic regions, will disturb the balance of Arctic ecosystems, including long-established plant-insect interactions. The cold-hardiness of Arctic insects, their greatest asset for survival in previous millennia, may very well become their greatest liability in the coming decades.

Abstract

The Arctic tundra biome has had a brief but highly variable history of formation compared with other world biomes, culminating in the modern northern flora and fauna that collectively maintain biodiversity connections on a global scale. Terrestrial Arctic tundra mammals constitute a fauna of approximately 80 species, to varying degrees adapted for life north of treeline. In addition to specializations for cold environments, Arctic mammals have evolved in response to dramatic climate cycling through the last 3 million years of the Quaternary period, developing life histories that reflect changing associations with other species and other biomes through time. This article focuses on evolutionary development of the modern Arctic tundra mammal assemblage, the environmental processes that have influenced their diversity and distribution across the northern hemisphere through time, and their collective ecology that drives continued community changes. In modern times, the Arctic is experiencing climate warming and associated anthropogenic environmental disturbances that are approaching the limits of what tundra mammals have experienced at any time through the history of this biome. Continued persistence of mammals within the Arctic tundra will depend on resilience and plasticity among species, and on concerted efforts by us to understand the processes that impact Arctic biodiversity in general. By doing so, scientists may anticipate focal species, local communities, or geographic regions at highest risk of population declines, investigate the consequences of changing species associations for competition, future evolutionary potential, and spread of disease, and ultimately manage and conserve these ecosystems and tundra wildlife more effectively.

Introduction

Mention of Arctic tundra will generally conjure images of a cold, stark, open landscape intermittently dotted with shaggy beasts fending off inclement weather, biting flies, or other shaggy beasts. These vistas (e.g., Fig. 1) often include pre-historic components of megafaunal assemblages that are now extinct and no longer interact within high latitude communities. Although large mammals continue to epitomize Arctic tundra landscapes, this classic view of mammalian tundra communities in the North is somewhat inaccurate, being under-representative of the diversity of mammals that contribute to a functional Arctic tundra biome today. This review focuses on all living (and some extinct) Arctic tundra mammal species and their environments through time from the perspective of both foundational and emerging research. These studies are refining our view of the environmental, ecological and evolutionary processes of change that have influenced Arctic species through the last 3 million years (Myr), and are providing informed predictions for future trends that may guide more effective management and conservation of tundra mammals and their associated communities (ACIA, 2005; Meltofte et al., 2013).

It is worth introducing this system through some definitions. The “Arctic” is variably defined as all land north of (a) the Arctic Circle, (b) the 10°C isotherm for average summer temperature, or (c) northern treeline. All are related, as global orbital processes govern seasonality, insolation, and the environmental conditions necessary for establishment or exclusion of boreal forests across latitude. However, a “north of treeline” view possibly captures best the current biotic associations of Arctic mammals, although this has certainly not been consistent through geologic time.

The term “tundra” is here defined in the context of most terrestrial (and non-riparian) habitats currently occurring north of treeline. Tundra communities as they exist today are characterized by flora and fauna that are adapted to cold environments, shallow wet-humic or dry-rocky soils built on surficial permafrost, with often prolonged winter snow cover, overcast and wet summers, and correspondingly short growing seasons. Despite an abundance of surface water, frozen conditions for much of the

Fig. 1 Artistic reconstruction of a Quaternary landscape within Beringia, illustrating a hypothetical mammalian community including steppe, tundra, and boreal associated species, having no modern analog. Original Artist: Mauricio Antón.

year combined with low annual rainfall translates to an arid biome relative to most others (Callaghan et al., 2004). This view of Arctic tundra is often confusingly interchanged with terms such as steppe-tundra, steppe, or tundra-steppe, particularly when considering pre-historical conditions at northern high latitudes. However, as discussed below, the abiotic criteria of shallow permafrost and often waterlogged soils in defining Arctic tundra is essential for interpreting changes in associated biotic communities through time (Guthrie, 2001).

Arctic tundra mammals are endothermic vertebrate species sharing ancestral mammalian features (i.e., hair, mammary glands) but often with uniquely derived adaptations for living through cold winters, wet summers and highly seasonal environments (Callaghan et al., 2004). This fauna is comprised of relatively few species (~80; Table 1) that may be found in tundra across the Holarctic, although only roughly a third of these are endemic to Arctic tundra. Most are either habitat generalists, widespread through northern latitudes, or are predominantly associated with boreal forest habitats, being found within tundra only near the northern forest edge. Two of the most iconic Arctic mammals, the polar bear (*Ursus maritimus*) and Arctic fox (*Vulpes lagopus*) only inhabit the coastal fringe of tundra, and are primarily maritime species spending much of the year on sea ice. The consequent mixing of species from distinct biomes has been a pervasive process through the history of the modern tundra mammal assemblage.

Despite a relatively depauperate fauna, the scientific literature on Arctic mammals is extensive, reflecting a broad spatial and temporal focus that has drawn evidence from across the earth and life sciences. Ecological associations among living species (such as trophic webs, species interactions, and requirements of climate, habitat and microhabitat) increase our understanding of how current communities function (Meltøfte et al., 2013). Paleontological studies have revealed much of the life histories of now-extinct mammals or extirpated populations of species that highlight changing distributions and faunal assemblages through time (Guthrie, 2001). Geographic origins and evolutionary relationships among mammal species can be interpreted from genetic or morphological signatures of modern species. A combination of current species distributions, ancestral fossil localities and paleo-environmental reconstructions reflect multiple prolonged episodes of isolation, reconnection, and interactions within northern biomes (Markova et al., 2009). Increasingly, comparative investigations of co-distributed species and particularly of co-evolved species, such as combined evidence from mammalian hosts and their parasites, are revealing exciting biodiversity perspectives of faunal assemblages through time that cannot be learned from individual species assessments (Hoberg et al., 2017). These collective studies include evidence of relatively rapid formation of new species through time, past extinctions, and the corresponding complexity of shifting interactions between mammals and other groups of species across the Arctic, and globally. Under the lens of multiple integrated scientific disciplines, the study of tundra mammals can help us to define the drivers of biogeographic and natural history of species from multiple biomes through time (Hoberg et al., 2003).

History, Biogeography, and Ecology—Development of the Arctic Tundra Mammal Assemblage Through Time

Ice-Age Climate

The Arctic tundra biome dates to the Late Pliocene, roughly 3 million years ago (Ma; Abbott and Brochmann, 2003). At that time, coniferous forests were distributed northward to the Arctic Ocean and global temperatures were higher than today, although climates were changing. Following development of a permanent Arctic polar ice-cap around 2.6 Ma (Knies et al., 2014), global climate transitioned into the Quaternary period, accompanied by cooling, and onset of a cyclic climate regime that has typified long

Table 1 Extant mammal species that occur in Arctic tundra, indicating distributions, ecological associations, and associated phylogeographic assessments. Introduced species are not considered

^aDue to continental differences in biogeographic history, most Eurasian species with steppic associations at the last glacial maximum currently occur south of the boreal belt in central Asia and are therefore excluded.

^bHabitat is designated in order of predominance within current distributional range.

^cBiome associations are designated as a best approximation of both glacial and interglacial phase associations through the late-Quaternary, as reflected by phylogeographic evidence of refugial persistence in the Arctic, peri-glacial fossil evidence, or from the most current literature that may reflect diet (e.g., grass or moss) or substrate (e.g., mesic or xeric) preferences.

^dFull phylogeographic study citations are provided in the *Reference* section. Regional phylogeographic assessments considering only lineages south of Arctic tundra are not included.

term environmental change up to the present. Cycles consisted of relatively short warmer (interglacial) climate phases transitioning abruptly to more prolonged cold (glacial) phases. In the mid-Quaternary (~800 thousand years ago [ka]) climate cycles changed in their regular periodicity from every 41 thousand years (kyr) to 100 kyr, and cycle amplitude also increased. These most recent and extreme climate cycles, particularly since the transition to longer and more intense phases, had profound consequences for the distributions, processes of diversification, and interactions among biodiversity (Hewitt, 1996).

Although global in scope, the impact of this Quaternary “Ice Age” was most pronounced in the Arctic. Not only did species need to endure colder conditions, but during glacial phases, build-up of regional glaciers and continental ice-sheets as well as changing local conditions forced species to shift their ranges repeatedly, and dramatically (Pielou, 1991). In response to each climatic oscillation between glacial and interglacial, local species populations could either move, adapt to local changes, or experience significant population declines, often culminating in regional extirpation or range-wide extinction (Gilg et al., 2012). Any of these outcomes would have resulted in changing evolutionary trajectories, essentially both promoting diversification in some areas while eliminating local diversity from others through time (Lister, 2004). Over 20 major climate cycles were recorded through the Quaternary, with many additional and influential stadials/interstadials (more minor intra-cycle climate fluctuations; Wooler et al., 2018), affecting significant evolutionary change among tundra mammals.

Quaternary Biogeography

The cyclic nature of Quaternary climate and associated habitat fluctuations might be visualized as a see-saw that within the Arctic has oscillated between cool, wet conditions during interglacial phases, and cold, dry conditions during glacial phases. It is important to note that our current global warming trend through the present interglacial (=Holocene) is still markedly cooler ($\geq 3^{\circ}\text{C}$) on average than pre-Quaternary climate (Brigham-Grette et al., 2013).

Each climatic transition to a glacial phase was characterized by a net annual accumulation of terrestrial snow and ice, developing over thousands of years into continental ice-sheets, corresponding lowered sea-levels, and exposed land-mass, causing a rearrangement of the distributions of terrestrial mammals and their associated habitats. In this way, greater than 3 vertical kilometers of ice was deposited over much of Canada during the last glacial maximum (LGM; 21 ka), displacing the resident mammals into ice-free glacial refugia around the periphery of ice-sheets. In North America, populations of many Arctic mammals were repeatedly displaced south during glacial phases into peri-glacial refugia all across what are now the northern contiguous United States, including both brown (*Lemmus trimucronatus*) and collared (*Dicrostonyx groenlandicus*) lemmings (Burns, 2004). Other populations were shunted to coastal areas where they persisted in sometimes cryptic refugial areas of exposed continental shelf that became submerged again during interglacial phases. In Europe, mammal populations similarly shifted to more southern or coastal refugia as ice-sheets repeatedly developed over northwestern Eurasia (Fløjgaard et al., 2009). At the same time that large portions of the Arctic were fragmented and unavailable to mammals during glacial phases, much of central and eastern Asia remained ice-free, and lowered sea-levels resulted in connections between previously isolated land masses, opening corridors for species movement. The prime example in the Arctic is the region known as Beringia (Hultén, 1937), an ice-free terrestrial region extending from northeastern Siberia eastward across the Bering Land Bridge to unglaciated regions of Alaska and the Yukon Territory. Beringia promoted the intercontinental spread and diversification of Arctic mammals repeatedly through the Quaternary (Rausch, 1963; Waltari et al., 2007).

Each transition from glacial to interglacial phase resulted in a change to net annual loss of snow and ice, gradually melting glaciers and ice-sheets. The Beringian land-connection between Eurasia and North America was repeatedly lost as sea levels rose by as much as 130 m worldwide. Although many exposed coastal-shelf refugia were re-submerged at these times, populations from around the periphery of ice-sheets could again expand to fill newly exposed mainland areas (Pielou, 1991).

These dynamic environmental changes through the Quaternary were a strong driver of diversification among all extant Arctic tundra mammals, as well as those that are now extinct (Graham, 1986). What has been much less clear until recently is what environmental conditions were optimal for the proliferation of the Arctic tundra biome and what processes were most influential in promoting diversification among tundra mammals.

Split Origins of Arctic Mammals

The earliest Arctic tundra habitats at the onset of the Quaternary are thought to have originated from arid and cold adapted alpine floras that occupied mountaintop meadows, or from plants associated with mesic grasslands and forests that persisted and spread above treeline following the retreat of tree species (Abbott and Brochmann, 2003; Hoffmann et al., 2010). Provided mammal species were not constrained by a reliance on trees, or tree resources, early Arctic mammals may have stemmed from forest, grassland, or alpine taxa, adapting to cooling climates and habitats as floral communities experienced turnover (Lister, 2004). Many tundra mammal species today may be found broadly through both forest and tundra habitats. Other mammals such as the tree squirrels *Sciurus vulgaris* in Eurasia or *Tamiasciurus hudsonicus* in North America, or their associated predators the pine marten (*Martes martes*) or American marten (*Martes americana*), respectively, remained specialized within forests and became part of modern boreal communities.

But as species became adapted to colder environments across the north, there was a key dichotomy, with two unique biomes developing as a consequence of Ice Age conditions, including both Arctic tundra and what is now known as “mammoth steppe” (Guthrie, 2001). The distinction between these two biomes is of requisite importance as they define not only the associated floras

and faunas, but also the time frames during which they repeatedly rose and fell from prominence through the Arctic (Sher et al., 2005; Kahlke, 2014). Arctic tundra spread broadly across the north during interglacial phases when conditions were cool and wet, supporting dominant plants and fungi such as mosses, lichens, forbs, tussock grasses and dwarf shrubs growing on waterlogged acidic soils. In contrast, the mammoth steppe was associated with colder, and very dry conditions during glacial phases, and was dominated by grasses and sedges growing in deep, well-drained and alkaline soils (Guthrie, 2001). It is difficult to imagine an expanse of wind-swept arid grasslands across the unglaciated regions of the Arctic through a glacial maximum, displacing forests as far south as Mongolia and China in Central Asia; this is likely because virtually all of the steppe biome is now gone, and with it, many of the mammal species that relied on these environments.

A fundamental concept based on most recent evidence of Arctic ecology is that tundra, despite being a “cold associated” biome, was likely most patchy and limited in extent during the coldest glacial phases, when instead the mammoth steppe biome predominated across the north (Guthrie, 2001; Rabanus-Wallace et al., 2017). At these times, tundra communities were seemingly restricted to mesic refugia associated with major river drainages and other low-lying areas. One such region in central Beringia has helped to solidify this view. Evidence from terrestrial core samples taken from different locations through central Beringia have unearthed fossil beetle remains (Elias and Crocker, 2008), pollen samples, and isotopic values that together allow us to recreate the boundaries of a “mesic buckle” through the last glacial phase (Guthrie, 2001). Glacial phase samples through this region indicated ground water and wet conditions that supported tundra beetles and plants, whereas other sites of the same age, particularly through western and easternmost Beringia instead supported species associated with steppe and with radiocarbon dates, floral and faunal evidence indicating extreme aridity (Sher et al., 2005; Elias et al., 2006). Over the entire unglaciated regions of the Holarctic, despite some isolated mesic areas, the vast majority of sites sampled from this time period reflect a predominance of mammoth steppe (Zazula et al., 2007).

Conversely, during interglacial periods, Arctic tundra was more widespread, allowing tundra mammals and their communities to expand ranges. As tundra spread, mammoth steppe retreated, and in its place, warmer and wetter climates promoted northward establishment of boreal forests and their associated mammals. These major floral changes were likely a strong driver of changing faunal distribution and diversity (Rabanus-Wallace et al., 2017).

Ecology of Arctic Mammals Past and Present

Wet Arctic tundra supports most of the mammal species north of treeline that we see today, including rodents such as the brown and Norwegian lemmings (*Lemmus sibiricus* and *L. lemmus*, respectively) that feed largely on mosses and wet grasses. Collared lemmings (*Dicrostonyx* sp.) forage for berries, and bark from dwarf shrubs growing on higher ground among freeze-thaw polygons, and Arctic ground squirrels (*Urocitellus parryi*) cache grasses, wet sedges, and forbs for winter hibernation in well-drained upland soils where permafrost is sufficiently deep for burrow construction. Soricine insectivores such as the barren-ground shrew (*Sorex ugyunak*) and tundra shrew (*S. tundrensis*) thrive in interstitial and subnivean spaces, eating abundant arthropods within tussock and shrub-tundra. The few extant megafaunal species include caribou (*Rangifer tarandus*), often ranging in dense herds, and muskox (*Ovibos moschatus*), both of which eat a variety of tundra foods including lichens and dwarf shrub browse. The combined foraging of both small and large herbivores can heavily impact the shallow-rooted and relatively fragile tundra flora (Ravolainen et al., 2011). Scars of caribou trails across the tundra are a legacy of their extensive migrations both in response to seasonal weather changes, and to track available food resources. Norwegian lemmings, as well as some vole species (*Microtus* sp. and *Myodes* sp.) can exhibit dramatic multi-year population cycles (Krebs et al., 2002). Population explosions may deplete food resources or increase predator densities, causing population crashes, and lagged recovery of both habitats and mammal numbers (Korpimäki et al., 2004; Ims and Fuglei, 2005). These herbivore populations are intimately associated with mammalian predator species that thrive through the northern tundra (Gilg et al., 2003). The grey wolf (*Canis lupus*) effectively hunts both large ungulates through cooperative pack behavior, and small rodents, depending on local supply through a given year. This versatility is perhaps reflective of the cosmopolitan historic distribution of wolves through the Northern Hemisphere. Equally versatile is the brown bear (*Ursus arctos*) that will graze, browse for berries, scavenge carcasses or actively hunt fish and other mammals, passing these learned skills through generations of young. Smaller predators include the ermine (or stoat; *Mustela erminea*) that can easily navigate the rugged structure of developed tundra in search of voles, their primary food source.

In contrast to Arctic tundra, the arid mammoth steppe largely supported grazing mammals. The hard, dry ground that provided substrate for growth of deep-rooted grasses also supported loading from hooves of heavy megafaunal species (Mann et al., 2013). As the name suggests, this steppe was home to the iconic woolly mammoth (*Mammuthus* sp.), and many other large grazers including steppe bison (*Bison priscus*), Yukon horse (*Equus lambei*), woolly rhino (*Coelodonta antiquitatis*), camels (*Camelops* sp.), saiga antelope (*Saiga tatarica*) and yak (*Bos grunniens*). Of these, only the saiga still persist in isolated populations, and the yak as a semi-domesticated animal, both occurring in central Asian arid grasslands south of the boreal zone. Predators also abounded through the steppe, including the wolf, scimitar cat (*Homotherium* sp.), Eurasian cave lion (*Panthera spelaea*) and short-faced bear (*Arctodus simus*). Again, only the wolf has survived to the present, with determinant extinctions of other hunting species accompanying loss of large mammal prey as the mammoth steppe gave way to Arctic tundra since the last glacial phase. Steppe-associated survivors of the Holocene transition are mostly smaller mammals. Predators such as least weasels (*Mustela nivalis*) hunted steppe rodents including narrow-headed voles (*Lasiopodomys gregalis*), Siberian voles (*Microtus hyperboreus*) and species belonging to many genera of arid-adapted small mammals. Examples include steppe lemmings (*Lagurus* sp., *Eolagurus* sp.), steppe voles (*Alticola* sp.), marmots (*Marmota* sp.) and jerboas (*Alactaga* sp.). Rabbit kin (lagomorphs), including hares (*Lepus* sp.) and pikas (*Ochotona* sp.) are also still

represented in steppe-like environments. All of these mammals persist through central Asia across remnant habitats. This region surrounding the mountains and plains of Kazakhstan, Mongolia, and northern China may constitute both a refugial area for steppe species, and also have served as a major geographic and evolutionary source of the mammoth steppe fauna through the Quaternary (Kahlke, 2014).

Much of what we know of the relationship of mammoth steppe and Arctic tundra in the context of their mammals is from paleontological investigations of fossil-rich sites such as caves and pits that are stratified through time as they collect dead specimens, providing sometimes well-defined layers of mammal remains along with other fauna and flora (Hopkins et al., 1982). Results of fossil surveys, dated using a combination of calibrating layer depth with radiocarbon isotopes, provide evidence of mammalian communities that have no modern analog, containing species associated with both Arctic tundra, boreal forests, and mammoth steppe that seemingly co-existed during glacial phases (Zazula et al., 2007). Whether tundra and steppe mammals did interact within diverse mixed assemblages is a matter of debate (Guthrie, 1982). Many mammal species are highly mobile, and may have been transient through an area rather than being a permanent resident. Some mammal species tend to be over- or under-represented in fossil deposits in relation to their densities across the landscape, giving an inaccurate impression of community composition (Graham, 1986). Additionally, many thousands of years of accumulation can often be compressed and partially mixed without the ability to resolve more fine-scale community changes across local landscapes over even multiple centuries of climatic variability.

More likely, these fossil deposits support the concept of an Arctic that has been highly variable and heterogeneous through time, where the three major high-latitude biomes of tundra, mammoth steppe, and forest formed a complex and shifting mosaic (Fig. 1; Graham, 1986; Lanoë et al., 2017). Relatively distinct mammal communities would have ebbed and flowed in their prevalence according to climatic variability, with the extremes of wet or dry conditions supporting more purely tundra- or steppe-associated faunas, respectively (Kahlke, 2014). An additional dynamic through multiple climate cycles is that species have progressively adapted to new habitats, eventually forming new lineages or species associated with different biomes (Hope et al., 2013a). The proximity of tundra and steppe habitats through glacial phases, or tundra and forest habitats through interglacials, would have provided abundant opportunity for ecological and evolutionary diversification (Zazula et al., 2007). It is also evident from modern day Arctic mammal assemblages that many species are habitat generalists, equally likely to be found in either Arctic tundra, or boreal forest regions. These species may be intermediates on the adaptive scale between specialized extremes, or simply less constrained by habitat affiliations than by climatic conditions (McCain et al., 2018).

Contemporary field surveys and studies of Arctic biodiversity spanning the major ecotone (environmental transition zone) between Arctic tundra and boreal forest biomes clearly indicate that (1) overall mammal diversity is higher in these areas of contact between biomes than purely boreal forest or Arctic tundra (Barrio et al., 2016), (2) habitat generalists are a major component of mammalian richness through the Arctic tundra, particularly across transition zones, and are predicted to contribute significantly to the dynamics of future Arctic biodiversity (Hof et al., 2012; Elmhagen et al., 2015), and 3) forest mammals are generally shifting northward as climate continues to warm, often faster than the establishment of tree species (Hope et al., 2015).

Research Priorities and Outlook

Mammals within Arctic tundra are not only a vital resource for local peoples and economies (e.g., Klein, 1970), but they are intimately connected with the broader Arctic biodiversity that collectively maintains functional Arctic ecosystems through time. In turn, intact tundra supports global linkages, through movement of avian, marine, and other taxa, and through source/sink dynamics of energy/nutrient transfer and long-term storage between and within atmosphere, land and oceans (Metcalf and Olofsson, 2015). Arctic biodiversity is low compared with most other biomes, and a broken connection through species decline or extinction, disruption of habitat and food resources through disturbance, or community turnover through invasion or introduction of nonnative species may have disproportionately negative and cascading impacts on one of the largest but most vulnerable of the world's biomes (Meltotte et al., 2013).

A principal value of studying tundra mammals is their usefulness as indicators of Arctic change (Hope et al., 2016). Most tundra mammals are resident year-round, highly adapted to northern environments, and sensitive to change through time. We can therefore use knowledge of how mammals have evolved in response to past environmental changes, assess current distributions through field sampling, monitor trends in population size and species traits such as genetic or phenotypic diversity, and consequently make more informed predictions for continued trends (Hope et al., 2013b). In association with understanding mammalian responses, it will be increasingly important to resolve the fundamental connections between mammals and other species both within the tundra biome, among other northern biomes, and globally.

Lineage Diversification, Warm and Cold Refugia, and Geographic Discontinuities

In the past three decades, the discipline of phylogeography has matured to effectively bridge the gap between the traditions of population genetics (analysis of intra- and inter-population diversity) and phylogenetics (higher-level evolutionary relationships) by resolving the evolutionary history of species across their geographic range on an intermediate timescale, roughly coincident with formation of species through the Quaternary (Avice, 2000). As such, phylogeographic studies have provided powerful insights on how Arctic tundra mammals evolve in response to their environments across space and through time. Since its inception, the field

has expanded to address more nuanced questions related to the processes of speciation, community assembly, risk of extinction and associated co-evolutionary consequences of change (Cook et al., 2017). Given that most Arctic tundra mammals have already been the focus of a phylogeographic investigation (Table 1), there is now great potential for synthesizing our knowledge of mammalian community dynamics of the Arctic tundra, and making informed predictions for continued population and species trajectories into the Anthropocene (Hope et al., 2015; Lanier et al., 2015).

A key advantage of phylogeographic inference is that studies establish regional centers of diversity both within and among species, and through time. Evidence based on DNA sequence data indicates that most species vary genetically across their range, often punctuated according to geographic discontinuities which may be congruent across multiple species. Classic examples of these dynamics from Arctic mammals include comparative assessments through both Europe (Hewitt, 2000, 2004) and North America (Rand, 1954; MacPherson, 1965; Shafer et al., 2010). Through time, dynamic climate change led to population fluctuations, and generated new lineages, which eventually became new Arctic species. But, as some lineages or species formed, others just as readily disappeared, such as evidenced from divergence and periodic disappearance of distinct lineages of collared lemmings (*Dicrostonyx torquatus*; Brace et al., 2012), resulting in local community turnover through time.

The refugia, geographic breaks, transition zones between biomes, and periodic corridors for movement of Arctic mammals varied strongly by climate phase (Figs. 2 and 3). A preponderance of evidence indicates that tundra mammal distributions (in contrast to arid steppe mammals) were most fragmented during coldest peaks of glacial phases. Within Europe and North America at these times isolated populations occupied refugia south of continental ice-sheets in peri-glacial mesic tundra, where permafrost (Vandenberghe et al., 2014) had developed. These southern pockets of tundra were in proximity to forest communities also shunted southward, forming mixed ecotonal species assemblages (Stewart and Lister, 2001; Markova et al., 2009). In largely ice-free Asia, glacial refugia were instead likely associated with lowland pockets of mesic tundra in major river drainages (Hope et al., 2011), and surrounded by mammoth steppe. Similarly, the mesic buckle of tundra in central Beringia was bounded by steppe habitats to both west and east (Fig. 2; Guthrie, 2001), allowing for generation of endemic tundra diversity (Cook et al., 2005). Such extensive occurrence of allopatry (isolation) of tundra mammal populations during glacial phases would have often resulted in relatively

Fig. 2 Hypothetical glacial phase refugia and source areas for Arctic tundra mammals (red ellipses). In addition are shown hypothetical southern refugia for boreal mammals (blue ellipses). Post-glacial expansion routes (arrows) indicate likely sources for recolonization. Other refugia (without arrows) were more likely either sink populations, not contributing to Holocene gene pools or long-term endemics. Evidence for potential refugia have been built from regional clustering of genetically distinct lineages across many species, and based on phylogeographic literature as listed in Table 1. Shading indicates recent (black) and maximum (grey) glaciation during Quaternary climatic cycles. Much of the ice-free land area during glacial phases would have supported steppe habitats. Fig. 3 Holocene (current) interglacial contact zones (discontinuities between distinct genetic lineages) coincident with geographic regions compiled from phylogeographic studies of Arctic tundra mammals (see Table 1). Additional phylogeographic structure for some wide-ranging boreal mammal species is omitted. Also indicated are select warm phase refugia for fragmented populations of tundra mammals occurring on islands, or insular patches of Arctic or sub-Arctic tundra surrounded by boreal forest habitat. Descriptive names for contact zones may also coincide with geographic barriers to dispersal during glacial phases: 1 = Eastern North America; 2 = Mid-continent; 3 = Columbia Plateau; 4 = North Pacific Coast; 5 = High Arctic; 6 = Eastern Beringia; 7 = Alaska Range; 8 = Bering Strait; 9 = Kolyma Uplands; 10 = Verkhoyansk Range; 11 = Stanovoi Range; 12 = Central Siberian Plateau; 13 = Ural Mountains; 14 = Scandinavia; 15 = Northwestern Europe. Shading indicates modern extent of permafrost. Adapted from Brown, J., Ferrians, Jr., O. J., Heginbottom, J. A. and Melnikov, E. S. (eds.). (1997). *Circum-Arctic Map of Permafrost and Ground-ice Conditions*. Washington, DC: U.S. Geological Survey in Cooperation with the Circum-Pacific Council for Energy and Mineral Resources.

small populations, and evolutionary divergence dominated by genetic drift (Provan and Bennett, 2008). During each transition to an interglacial phase, widespread population expansion and much larger populations among tundra mammals would have promoted continued diversification, including increased opportunities for adaptive selection.

Current Arctic mammal distributions offer the best evidence that at the onset of interglacial periods, previously isolated mammal populations expanded from refugia along with their tundra habitats, to near-continuous ranges across the Holarctic. However, as forested habitats shifted northward, some northern tundra regions became fragmented into modern tundra refugia, particularly along continental edges (Fig. 3; e.g., Stewart et al., 2010). In addition, not all glacial refugia were sources for post-glacial expansion, and phylogeographic studies can often also identify which refugial populations were sources (more often northern; e.g., Fedorov et al., 2003), versus sinks where populations were possibly repeatedly shunted, then extirpated through multiple cycles (Fig. 2; more often southern peri-glacial; Stewart and Dalén, 2008; Fulton et al., 2013). Additional complexity is often revealed from populations occupying coastal refugia during glacial phases. The best examples of these include once-exposed continental shelf in Ireland (Martínková et al., 2007), northern Scandinavia (Fedorov and Stenseth, 2001; Brunhoff et al., 2006), the High Arctic of North America (Fedorov and Stenseth, 2002; Waltari and Cook, 2005), or Southeast Alaska (Cook et al., 2001, 2006), all isolated between ocean and continental ice. Not only were these refugia generally small, leading to rapid genetic drift and bottlenecked populations, but as ice-sheets receded, isolation was maintained by rising sea levels, promoting long-term (multi-cycle) regional endemism among these insular mammal populations.

Holocene Environments and Anthropogenic Impacts

Holocene climate has been relatively stable by Quaternary standards, but global environments through the last century have been rapidly changing, with projected global temperature increases for the next century that may rival or exceed Pliocene (pre-Arctic tundra biome) temperatures (Hinzman et al., 2005). In particular, anthropogenic contributions to atmospheric carbon dioxide, methane, and other greenhouse gas emissions have enhanced a warming trend with disproportionately high rates through the Arctic, that have no analog within the last 3 Myr (Gilg et al., 2012). Humans (also a mammal associated with tundra) have been present through the Arctic since the last glacial phase, impacting other tundra mammal populations through to the present time (Kahlke et al., 2011; Wooler et al., 2018). Abundant archaeological evidence indicates that humans hunted tundra and steppe megafaunal species coincident with their declines since before the onset of the Holocene climatic transition (Lanoë et al., 2017). Now, a combination of rising human populations, increasing development through the Arctic, and global-scale industrial activities will likely have more far-reaching consequences for tundra biodiversity (Barnosky et al., 2012). Despite the anomalously high warming rate, we know that the previous Eemian (Sangamonian in North America) interglacial (130–115 ka) attained slightly warmer peak temperatures than at present, and forests had advanced northward to the Arctic coast in many places, fragmenting Arctic tundra populations, particularly for tundra specialist mammals. Present day climate models and projected species distribution models provide increasingly rigorous predictions that the circumpolar Arctic tundra will experience continued fragmentation in the coming century (Hope et al., 2013b). Mammals will be forced to respond to this modern warming. Shrinking Arctic tundra will in effect lead to modern refugia for tundra mammals and their communities (Stewart et al., 2010). A priority for scientists, land- and wildlife managers will be to locate refugial centers for the tundra biome, and focus efforts on regional conservation coupled with maintaining connectivity more broadly across the Arctic. A related threat is that predicted refugial areas for tundra wildlife may be coincident with regions of active or planned human development, particularly for access to abundant reserves of fossil fuels across the northern permafrost zone and the Arctic Ocean. Balancing the competing demands of human growth and economy with maintenance of intact wild systems will be a continuing challenge (Hope et al., 2013b).

Contact Zone Community Dynamics and Co-evolution

A productive setting for investigating interactive change among Arctic mammals is across contact zones. Contact zones are geographic regions where distinct populations, species, or communities meet (Fig. 3). Often these areas reflect secondary contact between previously isolated and reconnected flora and fauna (Swenson and Howard, 2005). Across the Arctic there are numerous longitudinal contact zones both within and among mammal species that help to delimit regional diversity (Fig. 3). In addition, latitudinal zones of contact occur between major biomes such as the ecotone between tundra and boreal forest that spans the Holarctic, or between northern tundra and the Arctic Ocean, connecting terrestrial and marine ecosystems. All of these dynamic regions may be considered natural ecological and evolutionary “experiments,” providing insight into the unique interactions between communities (Hewitt, 2011). Such interactions include competition for resources or space, interbreeding (hybridization) among lineages or closely related species, and transfer of parasites, pathogens and other materials.

Competition across contact zones is difficult to study directly, given that interactions among species of mammals, particularly small species, are seldom possible to rigorously assess in a field setting (Ale et al., 2011). However, through the Arctic, northward shifts of boreal plants and animals accompanied by displacement of tundra populations is being well-documented. Studies have also assessed the dynamics surrounding leading or trailing edges of species ranges and the associated diversity, adaptive potential, and competitive pressure (Hampe and Petit, 2005). Although boreal mammals at the leading (northern) edge of forest and shrubby expansion may have relatively low genetic diversity (Hewitt, 2000), these taxa also tend to be generalists, able to quickly fill available niche space. Resident tundra species with adaptations for tundra habitats could in theory have a competitive advantage (Svenning et al., 2014), but this may be balanced by continued climate warming, making local conditions progressively sub-optimal for more specialized cold-adapted tundra populations (Killengreen et al., 2007; Clavel et al., 2011).

Community mixing across contact zones is often accompanied by interbreeding between related taxa, resulting in gene flow between regions. The cyclic nature of Quaternary climate change caused progressively divergent lineages and species to reconnect and repeatedly hybridize through their history and this gene flow has been a pervasive evolutionary process, often detrimental, but also offering evolutionary potential (Bridle and Vines, 2007). Hybridization may lead to the homogenization of previously distinct genetic pools, or may reinforce divergence across contact zones if hybrid offspring are less fit for survival or only locally fit within the contact zone. Increasing evidence suggests that hybridization plays a pivotal role on the speciation continuum (Abbott et al., 2013).

Among Arctic mammals, gene flow has occurred across a number of longitudinal contact zones including the vicinity of the Kolyma and Omolon Rivers in Siberia between lineages of tundra voles (*Microtus oeconomus*; Galbreath and Cook, 2004), and the eastern edge of Beringia between divergent lineages of ermine (Colella et al., 2018). Perhaps more intriguing are instances of hybridization between tundra and boreal forest species during interglacial phases. Mountain hares (*Lepus timidus*) have interbred with multiple other hare species across the Northern Hemisphere (Melo-Ferreira et al., 2014). Red-backed voles (*Myodes rutilus*) have hybridized with congeneric forest species in both Eurasia (*M. glareolus*; Deffontaine et al., 2005) and North America (*M. gapperi*; Runck et al., 2009). Likewise Arctic ground squirrels (*Urocitellus parryi*) have interbred with their temperate relatives (McLean et al., 2016), and shrews (*Sorex cinereus* and *S. ugyunak*) are actively interbreeding across the boreal-tundra ecotone in northern Alaska (Hope, unpublished data).

Study of the dynamics of genomic mixing among species, and the impacts that this has on either or both of the parent species is only now being developed with the modern utility of genomic sequencing, but should greatly enhance studies of speciation, and of adaptive changes in response to changing environments (Colella et al., 2018). For instance, although boreal mammals were periodically extirpated from Arctic regions through Quaternary glacial phases as forest habitats shifted southward, it is likely that a legacy of hybridization from the previous interglacial was retained at high latitudes within tundra populations, with the potential to reconnect with successive boreal populations as they returned north during the following interglacial (Runck et al., 2009). Tracing the history of genomic signatures through time to recreate past community associations is an exciting future prospect. An insightful example of gene flow, speciation, and adaptive advantage of hybrids has been demonstrated through sequencing of both fossil and modern DNA from polar bears and brown bears. These studies suggest that hybridization may enhance survival in transition (contact zone) habitats, but with continued directional gene flow (introgression) eventually eroding genomic legacies from one species (here polar bears) in favor of the prevailing biome (Edwards et al., 2011; Miller et al., 2012; Cahill et al., 2018).

An emerging area of study across northern contact zones is the co-evolutionary dynamics between Arctic mammals and their parasites and pathogens (Cook et al., 2005, 2017). We can use knowledge of the relationships between mammal hosts and their parasites as proxies for understanding environmental change within Arctic tundra. In particular, parasites generally exhibit complex lifecycles that are governed at least partially by external environments. As host and parasite species are intimately associated through these life-cycles, they can be particularly valuable for interpreting generalizable biodiversity responses to accelerating change (Hoberg et al., 2012; Kutz et al., 2014). Parasites may be specialized for a given host mammal, or may more generally infect a broad diversity of mammals. But regardless of specificity, these diverse yet understudied organisms are highly sensitive to climatic variability, and may respond dramatically to threshold environmental changes, particularly via climate warming that both stresses mammalian hosts and facilitates parasite proliferation (Bradley et al., 2005). For instance, lung nematodes that infect muskox as the definitive hosts also require intermediate hosts such as slugs with parasite life stages occurring at ambient environmental temperatures. Until recently cold climates have limited parasite developmental stages to a 2-year life-cycle. But, as climate warms in the Arctic, these parasites can develop faster, resulting in annual life-cycles, amplified parasite loads in muskox and resulting increased morbidity and mortality (Kutz et al., 2004).

The evolutionary history of mammalian parasites through the Arctic has also been used as multiple lines of corroborative evidence for mammal phylogeographic histories, often paralleling patterns of host geographic colonization and diversification (e.g., Wickström et al., 2003; Haukioja et al., 2016a, b). Interactions between hosts and parasites may change as a result of host-switching (Koehler et al., 2009), mammal hybridization or simply population mixing that influences relative susceptibility of mammals to infection, or through changes in the relative pathogenicity of infections with changing environments (Kutz et al., 2014). Parasite histories also reflect previous host associations with mammal species that were locally extirpated or are now extinct, carrying forth a legacy of past Arctic mammal communities in the absence of host specimens (Rausch, 1994). An example, again with muskox, considers reinfection by another nematode species as a result of muskox being re-introduced to their historic range following overhunting in the 19th century. This nematode was transferred back to the muskox from Dall sheep, the latter an alternate mammalian host which successfully maintained nematode populations in this region until muskox established secondary contact and were re-infected (Kutz et al., 2004).

The vast Holarctic extent of Arctic tundra, interconnected mammal distributions, and a circumpolar transition into the boreal biome presents broad opportunity for global spread of mammalian parasites and pathogens. Future persistence of Arctic tundra mammals will depend both on species resilience and plasticity, and an increased understanding of the intimate biotic connections linking these “communities *within* communities” (Hope et al., 2016).

Future Prospects

A major hurdle to Arctic mammal research is incomplete knowledge of species distributions, both past and present. Much of this review highlights research that relies on samples from physical specimens collected across Arctic landscapes and archived in natural history repositories that vouch for the existence of species at a given locality and time. But the tundra biome is extremely remote, and field expeditions are generally both expensive and logistically challenging (Cook et al., 2017). Informed and effective conservation and management of Arctic mammal diversity will rely on continued expeditionary fieldwork through all Arctic nations, to strive for comprehensive geographic coverage, long-term sampling at a given locality, and rigorous sample sizes per site of existing mammal and associated parasite biodiversity (McLean et al., 2015). The potential for emerging mammalian disease is increasing globally as climate warms, non-native species introductions increase, native biodiversity decreases, long-separated communities progressively mix, and environmental thresholds for Arctic taxa are exceeded (Keesing et al., 2010). Integrating an increasingly advanced toolset across multiple disciplines with improved knowledge of species histories, current distributions, and biotic associations will improve potential for maintaining functional Arctic systems within a non-analog modern world (Hinzman et al., 2005).

A positive outlook given the scientific evidence is that most tundra mammal species have survived through multiple warm and cold climate phases as well as rapid transitions between the two. The current extent of Arctic tundra is close to its maximum, and although currently contracting, a future with intact Arctic tundra communities should be possible with limited future global temperature rise. Besides the cascading effects of continued global change and a warming Arctic, the biggest threat to mammals and their communities is an increasing human footprint through the Arctic (Hinzman et al., 2005). Predicting the location of future hotspots or modern refugia for Arctic diversity, developing a better understanding of the ecology of community interactions, and reducing local anthropogenic impacts through these regions may be our best chance for conserving mammalian diversity through

the Arctic tundra biome. The charisma of Arctic mammals and the affection that humans share for shaggy beasts of all sizes, and for yet-wild places epitomized by the tundra will continue to motivate efforts for enhancing conservation of Arctic biodiversity.

Abstract

The oldest evidence of human settlement in the western Arctic regions of Eurasia has been found at a site at 66°N in the Northern Urals, where people lived about 40,000 years ago. A site at the mouth of the Yenisei River was apparently occupied 45,000 years ago. Further east, in Western Beringia, there are two sites dating to about 40,000 years ago. The well-established age of these human occupations suggests that the Arctic region of Northern Eurasia was inhabited by humans during the interstadial warm period of MIS 3, about 50,000 years ago. All the evidence, including ancient DNA, indicates that the human occupation of the Eurasian Arctic was by anatomically modern people who had important advantages over Neanderthals. These early residents of the Arctic developed four critical innovations: obtaining food by hunting, the manufacture of clothing, housebuilding and transportation vehicles in the form of frame boats and dog sleds. Microblade technology developed only at the beginning of the Holocene, coinciding with the demise of the mammoth population.

Introduction

The continental regions of the Arctic are occupied by various kinds of tundra ecosystems, from polar desert, common in Eurasia along the coasts of the Arctic Ocean and some islands, to the relatively richer vegetation of shrub tundra and forest-tundra in the southern regions of the Arctic. Since the beginning of Arctic scientific research, about 400 years ago, European and Russian travelers and researchers have observed that all the Arctic regions have long been inhabited by humans, despite the harsh climate and the paucity of the natural resources.

It has been established that the cultures of Arctic peoples are excellent examples of human adaptation to the challenging conditions of the natural environment, and that these cultures have been quite stable throughout the region. Ethnographically, maritime adaptations developed in coastal areas, while the culture of continental hunters evolved from ancient hunting and gathering to reindeer herding, which became widespread across Northern Eurasia, but never reached Arctic North America. Harness dog breeding for use in sledge transportation has been a common adaptation among all Arctic aboriginal peoples. The physical evidence indicates that the indigenous people of the Arctic have lived there for a very long time.

Earliest Human Occupation of the Arctic

Archeologists have been trying to discover when people first came to the Arctic. The search for an answer to this question, despite more than a century of archeological research in the region, remains one of the most important areas of archeological research.

The first archeological excavations in the Arctic were carried out in 1787 by the Russian researcher Gavriil Sarychev. He searched for signs of prehistoric human occupation in a region east of the mouth of Kolyma River near Cape Baranov. However, systematic archeological study of the Arctic and subarctic territories started a century later, at the end of the 19th century. These studies were quite active between WWI and WWII. By the 1930s, the concept of a land bridge connecting northeast Siberia to Alaska was taking shape, based on botanical data collected by Swedish botanist Eric Hultén (1937). Since the end of WWII, the volume of archeological research in the Arctic has increased significantly. New archeological studies are being implemented in the 21st century, making use of an entire arsenal of recently developed methods.

The chronicle of human settlement in the Arctic begins about 50,000 years ago (Fig. 1). The human occupation of the Arctic represents the opening act of the last phase of the global settlement by anatomically modern humans. This resulted in the human mastery of the Arctic regions of Northern Eurasia, followed by human migration to the New World, the last part of the world to become inhabited. Humans spread across the Arctic territories of North America and Greenland, completing the process of human migration and settlement in the far north.

Thus, the Arctic territories were the scene of some of the most important events in the history of mankind. On the geological time scale, this process covers a significant portion of MIS 3 (57,000–29,000 years ago) and MIS 2 (29,000–14,000 years ago), culminating in the Holocene (MIS 1: 14,000 years ago, to the present day). The Holocene was mainly a time of redistribution of human populations in previously populated areas of the Arctic, often associated with the influx of new human groups.

These processes were driven by various abiotic and biotic factors, such as changes in plant and faunal associations, changing landscapes, changes in the forest boundary, and changes in the population dynamics of large herbivores, driven by climate. Changes in any of these components, which were in complex interaction, were significant for ancient peoples. Opportunities for the settlement of humans in different regions of the Arctic varied significantly in different areas. These opportunities were determined by the course of development of landscapes, flora and fauna, following the deglaciation of regions such as the Canadian Arctic and the coastal margins of Greenland.

The Arctic regions of the Eastern Hemisphere, apart from the area occupied by the Scandinavian Ice Sheet, were mostly available for human settlement during the late Pleistocene.

The cycles of glaciation are associated with global changes in sea level, which fell during glacial intervals and rose during interglacial warm periods. These sea level changes affected different regions of the world to a greater or lesser extent. They were most dramatic in the Arctic, where large areas of regional seas have broad, shallow shelves. When sea level fell, a large land bridge formed between Siberia and Alaska: the Bering Land Bridge (BLB). Also, the northern shores Arctic waters of northeast Siberia shifted considerable distances northward, exposing large regions of continental shelf. These changes in regional geography were extremely important for human populations, as they influenced, directly and indirectly, the spatial distribution and composition of plant and animal groups, and served as a factor in climate change, contributing to the strengthening of climatic aridity in the continental regions.

The oldest evidence of human settlement in the western Arctic regions of Eurasia has been found at the Mamontovaya Kurya site at 66°N in the Northern Urals, where people lived about 40,000 years ago (Pavlov et al., 2001). A site on the Sopochynaya Karga Cape, on the border of western and eastern Siberia at the mouth of the Yenisei River (Fig. 1), was apparently occupied 45,000 years ago (Pitulko et al., 2016). Further east, in the Siberian side of Beringia, known as Western Beringia, there are two sites dating to about 40,000 years ago: the Yana Upstream Point locality and the Bunge-Toll-1885 site (Pitulko et al., 2017). The well-established age of these human occupations suggests that the Arctic region of Northern Eurasia was inhabited by humans during the interstadial warm period of MIS 3 (Seierstad et al., 2014), about 50,000 years ago.

The MIS 3 Interstadial

In Arctic West Beringia this time interval was apparently warmer and wetter than conditions a few thousand years earlier, i.e., at the end of MIS 4. The region supported an ecosystem of open spaces that became dominated by grasses and forbs (Andreev et al., 2011), which in turn supported herds of megafaunal grazers, including woolly mammoth. The regional population of mammoths grew rapidly and reached an all-time peak at about 45,000 years ago (Andreev et al., 2011). The biome that formed is termed the Mammoth Steppe. Because it supported abundant populations of large game animals, it played a crucial role in the settlement of humans in Northern Eurasia (Fig. 3).

Identity of Earliest Arctic Peoples

The demonstrated antiquity of human presence in the Arctic zone of Northern Eurasia immediately raises the question of the identity of these people. They were living a relatively short time before the extinction of Neanderthals. There would have been sufficient time for Neanderthals to have moved into the Arctic before their extinction, perhaps responding to the pressure of being pushed out of more southerly regions of Asia by migration waves of the modern man. It should be noted that, with regard to Byzovaya site in Northern Urals, archaeologists did indeed suspect that this site was occupied by Neanderthals, based on the age of the finds and the morphology of a few artifacts (Slimak et al., 2010). However, this hypothesis has come under criticism (e.g., Zwyns et al., 2012). In fact, there is no reliable evidence for the settlement of Neanderthals or other archaic forms of *Homo* north of 55° latitude, either from any anatomical remains or any characteristic stone tools.

On the contrary, there is reliable physical evidence of the presence of anatomically modern people in the sub-Arctic region of Siberia during the Late Pleistocene (Fig. 2). One example is human bone, from the Ust-Ishim site situated at 57°N, which dates to 45,000 years ago (Fu et al., 2014). Physical remains of anatomically modern humans also come from the Yana site (Sikora et al., 2019).

However, lithic tools made by humans during the late Pleistocene across Northern Eurasia are characterized by a certain primitive, archaic quality (Pitulko et al., 2004; Svendsen et al., 2010). More precisely, the tools exhibit some roughness in their finish, and have simplified shapes (Pitulko et al., 2013). However, this says little about the highly developed culture of these people, which

represents a bone tool industry of the highest level and quality (Pitulko et al., 2012; Pitulko et al., 2015a), with developed sets of ornaments and ornamental systems, known from the materials of the Yana River site (Fig. 3). The people who occupied the Yana site led a mobile lifestyle, traveling hundreds of kilometers, presumably to exchange trade goods with other groups of people. For instance, the Yana site has yielded specimens of amber that most likely came from the New Siberia Island, 800 km north. As discussed below, in the treeless regions of the Arctic, mammoth bones and tusks were highly prized materials for the making of tools.

Important Technological Innovations

Thus, it is fair to conclude that human occupation of the Arctic regions is associated solely with anatomically modern people (Fig. 2) who had important advantages over Neanderthals. These benefits are repeatedly described as top-paleolithic innovations, listed by Mellars (2005). His list shows the 15 most important innovations. First, they are found in their material culture, reflecting the direct interaction of humans and the environment.

Fig. 3 Arctic and sub-Arctic archeological sites dated to 34,000–31,000 years ago (34–31 ka), and major environmental settings reconstructed for late MIS 3 based on data published in: Barr I. These important innovations include noticeable advances in stone tool processing technologies, such as the widespread use of blades, the emergence of new forms of scrapers and burins (an engraving tool with a diamond-shaped point), the appearance of improved projectile points for hunting, and the high level of production of bone and horn products. The latter include items of hunting equipment and needles. In addition to improvements to their material culture, these people also developed changes in behavior, such as improved hunting strategies and tactics, the emergence of a well-defined hunting specializations, and the production of materials that indicate complicated social behavior. Introduction of these technological innovations allowed anatomically modern people to master subarctic and then Arctic territories.

The innovations represented in Arctic archeological sites from the Late Pleistocene reflect the technological complexity of the culture of ancient people (Hoffecker and Hoffecker, 2017). One of the most important of these is the making of tailored clothes and other products from animal skins (Pitulko and Pavlova, 2019). The main technologies recognized by Mellars (2005) do not have a hierarchy, but in an Arctic context, the most important of these were actions directly related to the technology that allowed humans to survive the bitterly cold winters on the open tundra-steppe regions of northern Eurasia.

Primarily, three of the innovations are the most significant: obtaining food by hunting, the manufacture of clothing, and house-building. However, over time (probably in the later Pleistocene), they added a fourth important component: transportation vehicles in the form of frame boats and dog sleds. The hunting of large mammals supplied the raw materials (animal hides, sinews, etc.) to produce leather products. Hunting also supplied the animal bones needed to produce bone tools, of which the most important were hunting weapons and sewing needles.

In fact, sewing technology was obviously one of the two critical technologies needed for human occupation of the frigid Arctic. Key to the development of the sewing needle is the ability to create an eye, through which sinews may be threaded. The oldest of these (eyed needles) have been found in Siberia, where they have been found in numbers indicating mass production and use in MIS 3 (Pitulko and Pavlova, 2019). The presence of needles with an eye allowed the production of multi-layered clothing, sewn to fit the wearer, as well as the whole range of sewing products, including shoes, sleeping bags, soft containers and bags, and dwelling covers. Based on the evidence from the Yana site excavations, the dwelling structures were light ground constructions with inside hearths used to burn various fuels including animal bones. In Arctic regions that lack wood for fuel, people burned the bones of large animals, including mammoths. These bones contained greasy marrow that would burn.

The development of sewing technology is a prerequisite for successful human life in the subarctic and Arctic zones, where modern average annual temperatures vary from 0 to -16°C , and where any slight decrease global average temperatures will significantly worsen environmental conditions. Such changes have occurred repeatedly, of which the LGM and Younger Dryas Cooling are best known of the Late Pleistocene. But smaller-scale climatic changes were much more numerous (Rasmussen et al., 2014) and undoubtedly forced changes in the spatial distribution of humans, as well as driving certain changes in the material culture in response to environmental changes.

Life in a Treeless Landscape

Throughout MIS 3 and 2, the territories of Northern Eurasia were occupied by tundra-steppe vegetation, which had considerable variability in space and time (Figs. 1, 3–6). One of the dominant features was the complete absence of woody vegetation. This circumstance was extremely significant for the ancient people of the Arctic. Trees serve not only as fuel, but also as a building material used for the construction of the frames of dwellings, in addition to their use in the manufacture of hunting weapons, namely, the shafts of spears and darts.

In the case of fuel for burning, alternatives can be found in the Arctic, for instance, the use of branches of shrubs, peat, bones and fat animals for fuel. Alternative building materials for the frames of dwellings may be found in the large shoots of shrubs, which can easily reach 3–4 m lengths in warm microhabitats. However, much higher quality material is needed to make the shaft of a spear. Thus, the importance of wood as a cultural resource can only be fully assessed if it is not available at all. This is the situation that faced the first people who entered the Arctic tundra during the Late Pleistocene in the Eurasian Subarctic and Arctic.

To overcome the lack of wood, the Upper Paleolithic people, including inhabitants of the Yana River site, developed a special technology to longitudinally split the tusks of woolly mammoths. In this way they obtained strong shafts of ivory up to 2 m long - the length needed for the shaft of a full-size spear. Traces of this technology are documented in several localities across arctic Western Beringia including the Yana and Berelekh sites (Pitulko et al., 2015a). The ivory-shafted spears were needed to hunt large Pleistocene herbivores, including the mammoths from which the ivory was obtained.

Mammoth Hunting

Mammoth hunting was an important activity, but was carried out on a limited basis, primarily to obtain important raw materials, the tusks, bones and possibly fat, which, along with bones, could be used as fuel in winter. Mammoth meat was used for food but did not play a significant role in the diet of ancient hunters of the Siberian Arctic. Instead they hunted large numbers of Pleistocene bison, horse, and reindeer. There is no evidence of mass single-use mammoth hunting. Based on the fossil evidence, mammoth hunting was most likely carried out at a very low rate (1–2 animals per year) and was undoubtedly associated with the extraction of important bone raw materials (Nikolskiy and Pitulko, 2013; Pitulko et al., 2015a).

The mammoth population of Eastern Siberia experienced a notable decline in numbers toward the end of the MIS 3 interstadial, and during the LGM their numbers decreased even more. Pitulko and Nikolskiy (2012) suggest that mammoth populations

- sites dated to ~27–20 ka
- Eurasian Ice Sheet Complex at 27 ka (after Hughes, et al., 2015)
- Ice sheets at 22 ka: Eurasian Ice Sheet Complex (after Hughes, et al., 2015); North American Ice Sheet Complex (after Stokes, 2017)
- mountain glaciation margin at 27–20 ka (after Svendsen, et al., 1996; Glushkova, 2001; Barr and Clark, 2012; Galanin, 2012)
- dry land extent and land/sea boundary at 27–20 ka with ocean level decrease to -120 m (after Lambeck, et al., 2002)
- extent of the mammoth habitat in Alaska (after McDonald, et al., 2012)
- extent of the mammoth habitat in NE Asia (after Pitulko and Nikolskiy, 2012)
- extent of the mammoth habitat in West Siberia and in the Northern Europe (after Kahlke, 2014)

decreased from south to north in northeastern Siberia. It is noteworthy that this decline in mammoth numbers took place just as a new hunting technology was spreading northwards from Northern China and Mongolia. This new technology involved a newly invented lithic toolkit based on wedge-shaped core knapping. The northward spread of this technology was most likely due to human migration in eastern Asia, in response to the sharp cooling and increased aridity of the climate associated with the LGM. The growth of continental ice sheets and glaciers during the LGM also brought a lowering of sea level, exposing more of the continental shelf regions surrounding Northern Eurasia (Fig. 4).

Events of the Last Glacial Maximum

The quantity of archeological data used to evaluate the timing and processes of human settlement in the Arctic is quite large, but unevenly distributed (Hollesen et al., 2018). Thus, there are large chronological and spatial gaps in sites providing evidence of initial colonization (Figs. 4–6). As of this writing, there are no Arctic sites that provide a continuous, unbroken archeological record that documents the full history of human occupation of any Arctic. In some cases, such gaps span tens of thousands of years. For instance, in the Arctic zone of Northeast Europe, there is clear evidence for the presence of humans in the late Pleistocene prior to the Last Glacial Maximum (LGM), as evidenced by data from the Mamontovaya Kurya site, dated to ca. 40,000 years ago. There is also good evidence for human occupation of this region near the end of the last glaciation, based on data from the Pymva-Shor site, dated from 16,000 to 12,500 years ago (Svendsen et al., 2010), as well as evidence from the early Holocene, documented by a continuous archeological record that extends from northwestern Siberia to the Taimyr Peninsula. The dates of human occupation of these sites range from 8100 years ago in the west to 6800 years ago in the east (Fig. 7).

The best studied areas with a relatively short history of human occupation are northern Fennoscandia in the East (starting at 10,000–9000 years ago) and the American Arctic (starting at 13,000–12,000 years ago) in the Western Hemisphere. The vast Arctic territories of Northern Eurasia from the Barents Sea coast in the west to the Bering Strait in the east have been studied far less, but the existing data nevertheless allow us to assess the processes associated with human settlement of these regions in their essential details (Fig. 7).

Thus, LGM coastlines shifted north of their current position. Also, the desertification of the continental interior caused changes in vegetation cover, with northerly shifts of vegetation zones that would have caused redistribution of faunal populations. Of course, the hunter-gatherers of Arctic Siberia relied chiefly on these large herbivores for their food, so these animals served as a resource base for the human population of these areas. The LGM therefore caused environmental stress on the regional human population, forcing them out of their traditional hunting grounds. This, in turn, was the apparent driver for new weapon technology. The emergence of microblade technology, based on the splitting of wedge-shaped cores, is most likely a consequence of environmental changes associated with the disappearance of mammoth from the southern tundra belt of Northern Eurasia. As discussed above, mammoth tusks served as an important raw material for the production of hunting equipment, such as spear shafts (Pitulko and Nikolskiy, 2012).

It is important to note that despite the serious climatic deterioration during the LGM, the Arctic and subarctic territories of Beringia remained suitable for human life (Fig. 4), although the size of human populations, which had never been high, apparently became even lower. The human occupation of Eastern Beringia (i.e., unglaciated regions of Alaska and the Yukon) during the LGM is indicated by archeological evidence from Bluefish Caves, northern Yukon Territory (Bourgeon et al., 2017). However, it is difficult to interpret the culture of the Bluefish Cave population because of the lack of data.

In Western Beringia, reliable but rare traces of human activity during the LGM are known from the middle stretches of the Lena River at Khaiyrgas Cave site (Kuzmin et al., 2017) to the Yana-Indighirka lowlands in Arctic Siberia (Pitulko et al., 2017). Evidence of human occupation comes from radiocarbon ages of artifacts and sediments. In addition, ancient DNA evidence has recently revealed that the carriers of this culture were associated with a powerful influx of people from East Asia that completely replaced and/or assimilated the former populations of the ancient North Siberian population (“the Yana” people) (Sikora et al., 2019). This is in line with archeological evidence.

The main archeological features of their material culture are wedge-shaped cores, used to make microblades and bifacial spearheads. Beringian microblade technology first appeared regionally in the Amur Basin, approximately 24,000 to 23,000 years ago. In the interval of 18,000–12,000 years ago, this technology spread in the subarctic areas (e.g., the lower occupation component of Dyuktai Cave and the complex of layer 6 from the Ushki Lake), and rapidly spread to the Pacific coast. Thus, its earliest traces were found in Alaska, in the site occupation of Swan Point (cultural component 4), where it has an age of 14,500 years ago, as well as in several other sites, whose age is not less than 11,000 years ago. These latter sites belong to the Denali complex, dated to 13,500 years ago (Graf and Buvit, 2017).

Holocene History

It is noteworthy that in the Siberian Arctic region of Northern Eurasia, as far as can be judged by the evidence from dated archeological sites (Urez-22 and Tytylvaam IV), microblade technology developed only at the beginning of the Holocene, coinciding with the timing of the demise of the regional mammoth population (Pitulko and Nikolskiy, 2012; Pitulko et al., 2017). Artifact collections from the Tytylvaam site include both wedge-core and micro-prismatic technologies for microblade production. The stone tool industry from the Urez-22 site cannot be explicitly interpreted as wedge-shaped core technology. However, the morphology of the

Fig. 7 Selected Arctic and sub-Arctic archeological sites dated to 12,000–9,000 thousand years ago (12–9 ka); environment settings are shown for 9 ka time slice based on data published in: Binney, H. (2017). Vegetation of Eurasia from the last glacial maximum to present: Key biogeographic patterns. *Quaternary Science Reviews* **157**, 80–97; Dyke, A. S. (2004). An outline of North American

microblades suggests wedge-shaped technology was being used instead of prismatic knapping. Simplified wedge-core technology that post-dates the Pleistocene/Holocene boundary has also been found in other sites from various regions of Beringia, such as the Lake Baikal region, the Upper Kolyma region, and the Chukchi Peninsula, as well as in Alaska, where it is part of the Paleo-arctic tradition, and where it persisted until 5000 years ago.

The microblade tradition in Western Beringia was rapidly replaced in the beginning of the Holocene by microprismatic blade technology. Its earliest evidence is found in the Aldan river valley about ~12,500/12,000 years ago at Ust-Timpton site. However, at ~10,000–9000 the same technology was adopted in the eastern Chukotka (e.g., Ul'hum, Chelkun IV, Nivan sites). At ~9000 years ago, it reached the northernmost limits of the continent, as revealed by the microprismatic industry together with inset tools from the Zhokhov site (76°N, New Siberian islands). This is the oldest known archeological site in high-latitude Arctic (Pitulko and Makeyev, 1991). The regions in which this tradition was adopted extend from the Taimyr Peninsula in the West and to Bering Strait in the East, with an extension into NW North America. This stone tool tradition persisted through the first half of the Holocene (Fig. 7). According to the human genetics of the area, this phenomenon marks population changes due to migration from the southern areas to the Arctic (Sikora et al., 2019), driven by the sharp environmental deterioration of the Younger Dryas cold event in the deep continental regions.

The rapid northward advance of these populations was apparently due to progressive landscape change driven by several waves of the thaw-lake thermokarst development. The evidence indicates that it occurred after 15,000, ~10,500, 5000, and 2000 years ago, respectively. The first wave of immigration was the most powerful, followed by the northern shift of tree line. Thus, in Northern Eurasia, the herb-dominated tundra-steppe belt with open landscapes was largely replaced by forest. In the Arctic, steppe-tundra was transformed into dwarf-shrub tundra.

The cumulative impacts of environmental change at the end of the Pleistocene caused the steppe-tundra habitat to retreat northwards. The large Pleistocene herbivores, including mammoths, followed the steppe-tundra to the North, and the humans who exploited them followed after the megafauna (Pitulko and Nikolskiy, 2012). The last mammoths of continental Northern Eurasia persisted in the northern Taimyr and on the modern New Siberian islands until about 10,500 years ago (Nikolskiy et al., 2011). The Pleistocene horse and bison persisted in northern Eurasia somewhat longer (Lorenzen et al., 2011). It is likely that humans reached the northernmost limits of Eurasia following the animal migrations.

Reindeer is one of the species that survived the Pleistocene to Holocene transition. However, it likely suffered a serious reduction in population size at the onset of the Holocene. Because of the lack of large game animals, early Holocene Arctic hunters had either to develop a complex economy with elements of coastal adaptation where possible or seek unusual food resources.

Thus, the Zhokhov site provides evidence for year-round habitation based mostly on reindeer exploitation except in winter. In winter these hunters apparently killed polar bears in their dens (Pitulko et al., 2015b). Similar hunting tactics are widely known but the hunting of the world's largest terrestrial predator for use as a main food source has not been documented anywhere else in the world. The Zhokhov hunters must have had compelling reasons to hunt polar bears, e.g., limited availability of regular, or less dangerous, food sources.

Additionally, the Zhokhov site yielded the earliest reliably documented evidence for the use of a land transportation system based on dogsleds (Pitulko and Kasparov, 1996). Zhokhov dogs were physically identical to modern sled dogs by body weight and size. Apparently these dogs had been bred for sled hauling over a long period of time (Pitulko and Kasparov, 2017). The ancient sleds had well-developed construction with socketed uprights supporting the platform in a style similar to recent (ethnographically known) patterns. Indirectly, presence of such complex constructions also suggests the possible use of frame boats.

Introduction of the dogsled transport system is the most important innovation in Arctic human culture at the Holocene boundary. This element of adaptation allowed the early Holocene hunters of the Siberian Arctic and northwestern North America to move quickly over vast areas, adapting to changes in resource availability. They would also have obtained the ability to develop long-distance exchange systems. Geochemical signatures of obsidian artifacts from the Zhokhov site (Pitulko et al., 2019)

demonstrate that the source stone came from ~1500 km east of the archeological site, on Krasnoye Lake in the lower reaches of Anadyr river (Fig. 8).

The amount of obsidian found at the Zhokhov site is negligible compared with the quantity of the local chert. Since there is no evidence for any particular use of the obsidian, the real purpose of the developing contacts with people in remote areas may not have simply to facilitate exchange of goods. The driving force may well have been intellectual interest, rather than material gain. These findings indicate not only the existence of long-range exchange systems ~9000 years ago but speak of complex socio-cultural interactions that existed over vast areas.

The deposit on Krasnoye Lake is major obsidian source on the Siberian side of the Bering Strait (Kuzmin, 2019). Rocks imported from this obsidian source indicate that stable regional exchange networks existed throughout the Holocene. In addition to the Zhokhov site, this obsidian has been found at archeological sites on the lower reaches of Kolyma, in Chukotka and Kamchatka. Trans-Beringian imports of this obsidian into Alaska are also noted, but in low numbers.

The earliest evidence of human occupation of northern Scandinavia (Finmark) is dated about 10,000–9000 years ago (Olsen, 1994). By this time the first settlers were mastering shoreline resources (Fig. 8). The diet of the early Holocene population of the North Atlantic coast of Scandinavia shows a well-developed marine adaptation, as opposed to the population of the southern and eastern regions of Scandinavia, where the economy combined terrestrial and freshwater resources with a notable contribution of terrestrial foods. The diet of the inhabitants of the coasts of Scandinavia and the Kola Peninsula became more diverse with time, but with well-expressed elements of marine adaptation, as reflected in fossil remains (e.g., shell middens) and rock art. However, this adaptation never became as specialized as the maritime adaptations of the ancient cultures of the Bering Strait, the Canadian Arctic and Greenland.

Even after the early postglacial inundation of the continental shelves in the Eastern Siberian Arctic, the evidence for marine adaptation by regional populations begins only about 3500 years ago, and even this evidence is based on a single site: the Devil's Gorge site on Wrangel Island (Dikov, 1988). It is noteworthy that around the same time of the establishment of a maritime economy on Wrangel Island, the isolated population of dwarf mammoths (Vartanyan et al., 2008) died out. However, the human contribution to this event remains unclear.

Nevertheless, the Neolithic culture of North-East Asia may have certain connections with the Arctic Small Tool tradition. Genetic data indicate that back migration from Alaska and the Aleutians to northeast Asia took place about 5000 years ago (Sikora et al., 2019). Similar reverse migrations took place more recently, likely due to population growth in the Bering Strait area during warm intervals (Fig. 9), e.g. at ~2000 years ago (Roman Warm Period) and ~1000 years ago (Medieval Warming). Both intervals are clearly marked in the archeological record, by the emergence of the Old Bering Sea culture, and by the less known spread of the

Fig. 9 Selected Arctic and sub-Arctic archeological sites dated younger than 9000 years ago, and major coastal migrations in the Arctic: (a) postglacial migration(s) into Scandinavia; (b) Arctic Small Tool tradition spread into Alaska, Canadian Arctic and Greenland at around 5000 years ago; (c) Old Bering Sea culture spread to the west of the Bering Strait about 2000 years ago; (d) Thule migration ~1000 years ago; (e) migration to the west of the Bering Strait contemporary to the Thule migration.

Eskimo culture to the Kolyma river mouth (Pitulko and Pavlova, 2016), which was contemporary with the Thule migration into the Canadian High Arctic. Thus, possible cultural connection between northeast Asia and Thule advance into northern Canada may provide evidence for the earliest phase of that cultural pulse, but not its ancestry.

Bronze Age

Although Bronze Age metal artifacts are rarely found in Arctic and sub-Arctic archeological sites (Fig. 10), there is indirect evidence for introduction of metal tools before they appeared in the archeological record. It may be seen in the degradation of lithic

Fig. 10 Introduction of metals into the Arctic regions: possible directions of exchange systems with metallurgical centers of the Eurasian metallurgical province, Siberian metal trade route, Bronze Age metalworking sites in the Arctic (Sandvika, Ust-Polovinka, Abylaakh), and the earliest finds of iron working in the Arctic at Ust-Polui, West Siberia.

microblade industries starting ~4000 years ago, even though technologies had been thriving for millennia elsewhere in the Arctic. Since that time, the degradation in regional lithic industries developed rapidly.

Indirectly, this also indicates a stable long-range exchange between the people of the Arctic and the people who developed Bronze Age metallurgy centers in the Eurasian Steppe Belt. This trade allowed arctic peoples to acquire the most desirable sort of tools, i.e., products with a long sharp cutting edge. This acquisition of bronze cutting tools eliminated the need for mass production of blade inserts for composite tools. Thus, in the Northern Urals the blade industry was replaced by flake-based technology about 4000 years ago. This highly developed bifacial technique still survives in this region today. Not far from this region, about 1000 km away, there were metal working centers in the Kama river region and in the Middle Urals. In East Siberia, Ymyyakhtakh Late Neolithic culture has been identified, with highly developed lithic technology, including blade production. But ~3000 years ago, prismatic knapping technology was replaced by flakes. The Baikal Lake region may have been a source for metal imports into northeast Siberia. The two regions are connected by an ideal transportation system along the Yenisei and Lena rivers.

Metal working technology is extremely rare in the Arctic (Fig. 10). In the early metal era, bronze casting is recognized in Scandinavia by the discovery of molds made of soap stone. The earliest traces of this technology are probably at least 3800 years old. The northernmost find comes from the Sandvika settlement at 70°N, dating to ~3000–2500 years ago (Arntzen, 2015). However, the earliest bronze casting in the Arctic was recorded at sites on the Taimyr Peninsula, north of 70°N. These are Abylaakh and Ust-Polovinka sites whose ages are ~3200 years ago (Khlobystin, 2005).

Fig. 11 Climatic, environmental, and archeological record of the East Siberia versus paleogenetics of Beringia: (a) the NorthGRIP $\delta^{18}\text{O}$ profile and the Greenland Interstadials (GI) 1 to 13 (after Svensson, et al., 2008), blue bars indicate approximate positions of the Younger Dryas (YD) and Heinrich events H1 to H5 (after Tierney, et al., 2008); (b) summary pollen diagram (percentages are based on total sum of pollen and spores identified at each level) and biome zones derived from the PG1755 core record (based on Müller, et al., 2010); (c) annual precipitation and (d) mean temperature of the warmest month (based on Tarasov, et al., 2013, dashed lines indicate most probable values and gray bands show range of the best modern analogues for each reconstructed variable, along with the NorthGRIP $\delta^{18}\text{O}$ profile); (e) archeological record, East Siberia; (f) demographic modeling of Siberian and Native American populations: inferred parameters for model with Siberian and Ancient Beringian populations, dates of events are given as (ka), and admixture estimates are shown as percentages along the arrows (modified from Sikora et al., 2019). Iron Age

Early examples of iron working in the Arctic are even rarer than that of copper and bronze (Fig. 10). The only object whose age corresponds to the early spread of iron working technology is known from the Ust-Polui complex in the lower reaches of the Ob river, West Siberia dated to ~2500 years ago (Vodyasov et al., 2017).

The penetration of metals into Arctic Siberia is associated with another wave of human migration into the region, stimulated by the progressive cooling of the early Neoglacial, about 4200 years ago (Wanner et al., 2011). The arrival of peoples who knew the secrets of metalworking came somewhat later. This took place about 3500 years ago and coincides with a southern shift of treeline (Binney et al., 2017) that culminated with the establishment of its current position in Northern Eurasia (Payette and Lavoie, 1994). As this new forest-tundra boundary became established, so did new regional cultures: the classic deer hunter cultures of Northern Eurasia.

Conclusions

The main events and processes related to the settlement and life of modern humans in the Arctic are discussed above. It is easy to see that the human history of Arctic Eurasia is closely associated with both the largest paleogeographic and geological events in the history of the region, as well as less visible climatic changes. An example of the longest occupied site in the archeological record of Eastern Siberia shows that changes in the material culture were closely tied with climate change (Pitulko and Pavlova, 2016; Pitulko et al., 2017). These climatic variations drove changes in vegetation and landscapes, which in turn brought about changes in the composition and abundance of the regional fauna (food resources). The series of environmental changes were a driving force in the replacement of the original population of inhabited areas with new groups, mostly coming from the southern regions (Fig. 11). This process was repeated across the Eurasian Arctic.

In the Stone Age, the population of the Siberian Arctic hardly exceeded modern numbers. Perhaps only 50,000 people inhabited this region in antiquity. Even if this figure is greatly underestimated, it can be doubled, but 100,000 people also represent an extremely low population density, which appears to have been the case. In comparison, the Upper Paleolithic population in Europe is estimated to have been higher. Modeling of human population trends based on the spatial distribution of archeological sites during several time slices from 30,000 to 13,000 years ago suggests dramatic population declines during the LGM and consistently low population density in the northern areas. Human population density in more temperate regions, such as the Mediterranean, are estimated to have been one person per 100 km² at best (Tallavaara et al., 2015). But even this meager population level was much higher than it was in the Arctic.

Abstract

The first entry of people into northwestern North America in the Late Pleistocene was a highly significant event in the history of the spread of humans across the planet. Many questions remain to be answered concerning the timing of people entering North America, their origins, what caused them to leave Siberia and cross the Bering Land Bridge, and where did they manage to survive the extreme environmental conditions of the Last Glacial Maximum? Part of the problem in addressing these questions is that some key elements of the story very likely took place on the Bering Land Bridge (BLB), the exposed continental shelf regions that linked northeastern Siberia with Alaska during the last glaciation. Since the land bridge flooded near the end of the last glaciation, any evidence of human occupation there is now deeply submerged in the Bering and Chukchi Seas. We discuss these topics in turn and devote the remainder of this review to examining the peopling of Arctic North America during the middle to late Holocene.

Introduction

The first entry of people into northwestern North America in the Late Pleistocene was a highly significant event in the history of the spread of humans across the planet. The Americas were the last continents to be entered by our species, and apparently the gap between the human occupation of Eurasia and the eventual entry into the Americas was tens of thousands of years. The only region where Eurasia and North America are close together happens to be in the Arctic, probably the least hospitable region for human beings that evolved in the tropics. Yet we now know that at least two sites (and probably many more) in northeastern Siberia were occupied by anatomically modern humans, at least 50,000 years ago (Figs. 1 and 2). They hunted megafaunal mammals, such as mammoth, horse, bison and reindeer. They developed a rich material culture including many specialized tools and weapons made of mammoth tusk ivory. These Paleolithic residents of the Siberian Arctic apparently remained in that region until the climatic deterioration associated with the onset of the Last Glacial Maximum (LGM) drove them to seek new hunting grounds further east. These are the demonstrable archeological facts that secure our understanding of the colonization of the Siberian Arctic, but the subsequent sequence of events concerning one or more groups of people leaving their homeland and traveling east to the Bering Land Bridge and eventually onto the North American continent remain obscured.

Many questions remain unanswered. When exactly did these people enter the New World? Who were they? What drove them to leave northeastern Siberia? Which migration route did they use? Where did they reside during the Last Glacial Maximum (LGM)? What route did they take to leave Alaska and migrate south to the temperate latitudes? These all remain open questions, but one starting point may be found in the Beringian Standstill Hypothesis.

The Beringian Standstill Hypothesis

According to the Beringian Standstill Hypothesis, a population of anatomically modern humans migrated east from Western Beringia, onto the Bering Land Bridge (BLB). Based on the level of genetic differentiation between modern natives of northeast Siberia and Native Americans, this population was genetically isolated from its source population in Northeast Asia at the beginning of the Last Glacial Maximum (LGM), about 30,000 years ago. The Beringian LGM population carried distinctive DNA. After the LGM,

Fig. 2 Dated finds of anatomically modern humans discovered in the arctic Siberia, in the New World Arctic and in adjacent regions, largely used in paleo DNA studies to model human settlement of the New World Arctic regions in the past.

about 14,000 years ago, the descendants of this isolated population spread into mid-latitude North America and South America, although the DNA evidence indicates that some of the “standstill” population moved back into Northeast Asia (Hoffecker et al., 2016). There is also DNA evidence for another migration of people from Northeast Asia into North America, following the LGM.

The genetic evidence of the Siberian ancestors of the “standstill” population (Fig. 3), based on a study of ancient DNA from human remains at the Mal’ta site (24,000 years ago) and from the Afontova Gora site (17,000 years ago). The genetic evidence demonstrates the contribution of the Western Eurasian Lineage (Raghavan et al., 2014). The ancient DNA extracted from human remains at these two sites provides evidence in agreement with the aDNA evidence recently obtained from human remains at the Yana River site in Arctic Siberia (Sikora et al., 2019). All three sets of human genomes show great genetic diversity.

The people of the Yana River site, or Ancient Northern Siberians, made a significant contribution to the genome of the ancient Beringian population that colonized the Americas (Sikora et al., 2019). The population of Beringia was formed as a result of a mixture of the genetic lines of the ancient local population and the East Asian population (Fig. 3). This is indicated from genetic evidence from either side of the Bering Strait. In Siberia, a large fragment of human skull from the Duvanny Yar site (Sikora et al., 2019) yielded aDNA whose closest match comes from human remains at the Upward Sun River site in central Alaska (Moreno-Mayar et al., 2018), as well as the genome of modern Native Americans. In turn, in the first half of the Holocene the ancient Paleo-Siberian population (the Kolyma1 genome), was replaced by a new wave of East Asian origin - the ancestors of the modern

Fig. 3 Human interactions in the late Pleistocene Beringia: (A) Demographic modeling of Siberian and Native American populations and (B) Major hypothesized migrations into northeast Siberia before 30–10 ka based on data published in: Sikora M, Pitulko VV, Sousa VC, Allentoft ME, Vinner L, et al. Tunguso-Manchu peoples, who are most closely related to Evenks, the most widespread ethnic group among the present-day Siberian natives (Sikora et al., 2019).

As discussed above, the Beringian Stand-Still model (Fig. 3) is built mainly on genetic evidence. The DNA of the ancient “stand-still” population contains a significant number of genetic mutations that took place after these people left their Asian parent groups, but before the Beringian population spread throughout North and South America. These mutated genes are widespread among living Native Americans in mid-latitude North America and South America. Based on human genetic mutation rates, Tamm et al. (2007) calculated that the people who became isolated from their Asiatic ancestors remained in isolation for about 10,000 years before they began to disperse throughout the Western Hemisphere.

Dispersal Routes Out of Alaska

Additional, independent information that may have a bearing on the Beringian Standstill Hypothesis comes from recent computer modeling of the Cordilleran and Laurentide ice sheets, which coalesced in western Canada, sealing Beringia off from a land route to the lower latitudes of North America. The glacial model suggests that these massive ice sheets completely blocked any possible

interior route from Alaska and the Yukon to more southerly regions during MIS 3 and MIS 2, i.e., from about 55,000 to 15,000 years ago (Stokes et al., 2012). In other words, it appears unlikely that there was a human population in either mid-latitude North America or South America before 15,000 years ago. It also appears extremely unlikely that humans entered these regions prior to 50,000 years ago, because there is no evidence for humans in Northern Asia at that time (Fig. 1), so there would have been no founding populations from which to draw any north Asian migrants into the New World. Thus, the archeological, glacial and genetic evidence, taken together, suggest that a population of modern humans, descended from Asian peoples, became geographically and therefore genetically isolated for 10,000 years or more, before they had the opportunity to migrate south to the ice-free regions of the Americas. Also, most of the time estimates for the genetic divergence from this isolated population to their Native American descendants suggests that this dispersal happened after 15,000 years ago, which is consistent with the glacial chronology (Hoffecker et al., 2016).

However, in contrast to the interior ice-free corridor route, Lesnek et al. (2018) proposed that the initial departure of people Beringia took place as early as 16,000 years ago via a deglaciated corridor along the North Pacific coast (Fig. 3). Of course, such a route was only feasible if the western edge of the Cordilleran Ice Sheet (CIS) had retreated by that time, and if a coastal route was habitable, in terms of biological resources (marine and/or terrestrial) along the coast. The authors used ^{10}Be exposure dating and ^{14}C dating of bones from a cave in order to date the culmination of maximum CIS conditions in southeastern Alaska, a potential bottleneck region for human migration. These dates fell within the window of ~20,000 to 17,000 years ago. They also found fossil evidence that productive marine and coastal ecosystems were established almost immediately following deglaciation, after 17,000 years ago. They concluded that the retreat of the CIS provided an open and ecologically viable pathway for humans to travel through southeastern Alaska, which may have been traversed by early humans as they colonized the Americas.

Changing Arctic Environments

What drove the Late Pleistocene people of northeastern Siberia (Fig. 1) to abandon their territory during the LGM, 30,000–16,000 years ago? Even if they could have withstood the extreme cold and/or aridity that descended on Siberia during the LGM, it appears likely these climatic changes caused serious declines in the game animals hunted by these Western Beringians. The environmental changes caused shifts in regional vegetation cover, which in turn affected the large grazers. The cold, dry climate would have lowered the Net Primary Productivity (NPP) of the ecosystem. NPP is the rate of carbon uptake by plants from atmospheric CO_2 , minus the carbon used by the plants in respiration.

Pollen data indicate that NPP was greatly reduced in the continental regions of both Western and Eastern Beringia during the LGM. This sharp decline in NPP probably pushed the human population of Western Beringia over the edge of sustainability, as their prey animals dwindled on the landscape.

One of the effects of the build-up of continental ice sheets during the LGM was to draw down global sea level. Because of the very shallow seas between Siberia and Alaska, when the LGM sea level dropped about 120 m, it exposed a significantly larger area on the BLB (roughly 1.4 million km^2) than existed in MIS 3. Much of the newly exposed land was in the southeastern margin of the land bridge, the Bristol Bay region. This region is well south of the Arctic, falling between about 56–58°N. Modeling of LGM NPP showed a relatively high level of plant productivity in this southern region of the land bridge. It would have been not only warmer than Arctic Beringia, but it also received far more moisture, because it was adjacent to the North Pacific. Furthermore, ocean temperature reconstructions suggest that sea surface temperatures were only slightly cooler than today in the Bering Sea and the Gulf of Alaska. The continental shelf regions, newly exposed during the LGM, formed a relatively low relief plain where rivers meandered across a poorly drained landscape. This would have increased the available moisture on the landscape. Hoffecker et al. (2016) contend that the LGM actually created new habitat for hunter-gatherer peoples on the southern portions of the BLB.

A Possible Human Refuge on the Land Bridge

In recent decades, a substantial body of proxy data on Beringian LGM environments has been collected (Fig. 4), including information from sediment cores drilled into the former surface of the land bridge. These data, including pollen, plant macrofossils, and insect fauna, confirm the presence of a mesic tundra environment, not only on the exposed Bering Platform, but also extending into adjoining lowlands of Chukotka and Alaska. Even the more arid, steppic areas outside central Beringia supported a higher tundra component than was previously thought. Based on paleobotanical data, there were no trees growing anywhere else in Beringia during the LGM, but there is pollen evidence that the southern parts of the BLB supported the growth of spruce, birch, and alder (Westbrook et al., 2012). The insect fauna from central Beringia indicates a smaller decline in temperature (3–5 °C) than that estimated for many other parts of the Northern Hemisphere (Elias, 2001). The combination of warmer temperatures and greater precipitation in the southern areas of the BLB would have facilitated the growth of these boreal tree taxa.

The modeling of NPP for LGM Beringia described above, complemented by the other paleoenvironmental data, allows us to address the question of whether the LGM environments of the southern BLB could have supported a sizable human population. The paleoclimate model output suggests that there was a relatively productive NPP zone in the southeastern margins of the land bridge.

Fig. 4 LGM environments in the Arctic and near-Arctic regions in Siberia and NW North America, and archeological sites dated to 27,000–20,000 years ago (27–20 ka) based on data published in: Barr ID and Clark CD (2012). Potential Size of the Isolated Population

How many people were in this isolated group that had little or no contact with other peoples? A recent estimate of standstill population size, based on genetic diversity and substitution rates, concluded that at least 1000 people lived on the BLB (Mulligan and Kitchen, 2013). However, a total population of 8000–10,000 is considered possible. The NPP of the southern BLB would have supported a population of hunter-gatherers at a density of at least 2.5 individuals per 100 km². At this level, a standstill population of 5000–10,000 individuals would have required a territory of about 125,000 to 250,000 km², but this would have represented, at most, 20% of the area of the BLB (Hoffecker et al., 2016; Hlusko et al., 2018).

How did the “standstill” population survive the LGM? If they were concentrated in settlements at or near the southern coast of the BLB, then they had access to the coastal and marine resources offered by the North Pacific, which would have included shellfish along the shore, and fish and marine mammals out to sea. But these people had a deep cultural heritage of megafaunal mammal hunting, and it seems unlikely that they would have abandoned big game hunting completely. However, if the paleoecological reconstructions are correct, then the southern sector of the BLB was mostly covered in mesic tundra, a habitat unsuitable for large grazers because of the lack of grasses and forbs. It would thus appear that the hunters would have been forced to travel to the upland regions adjacent to the BLB to find their megafaunal prey. We are now getting a glimmer of evidence that megafaunal mammal hunting parties did travel to the interior of Eastern Beringia. Interestingly, the only clear-cut evidence of this comes from a site in the northeast corner of Eastern Beringia, at Bluefish Caves.

Hunting Excursions in Eastern Beringia

Bourgeon et al. (2017) re-evaluated the artifacts and faunal remains from Bluefish Caves, a site in the northwestern part of the Yukon Territory. It appears that the Bluefish Caves (Fig. 4) were used only occasionally as a short-term hunting site. The lithic assemblages recovered from the site include about one hundred artifacts, including microblades, microblade cores, burins and burin spalls. While the artifacts cannot be dated with precision, they are similar to the tools of the Dyuktai culture of Western Beringia. In Siberia, Dyuktai sites range in age from about 15,000 to as old as 22,000 years ago.

The most important finds made by Bourgeon et al. (2017) were 15 bone samples with clear indications of cut marks made by humans. These cut marks, indicating locations on an animal carcass where meat or sinews were cut away from bone, were observed on specimens representing Pleistocene horse (*Equus lambei*), caribou (*Rangifer tarandus*), elk (*Cervus elaphus*), and possibly Dall sheep (*Ovis dalli*) and Pleistocene bison (*Bison priscus*). These were apparently the most common game animals hunted by the people who came to Bluefish Caves. Six of the cut-marked bones were selected for AMS radiocarbon dating. The results range between 12,000 and 24,000 cal BP. Thus, the Bluefish Caves site clearly shows that people were in Eastern Beringia during the LGM, by at least 24,000 cal BP. This site provides long-awaited archeological support for the “Beringian standstill hypothesis” (Tamm et al., 2007).

Late Glacial and Early Holocene Sites in Alaska

The findings from Bluefish Cave indicate the presence of humans in the North American Arctic during the LGM. The artifacts from Swan Point (component 4), while somewhat younger, reflect the earliest cultural manifestation in Alaska with an archeologically distinct appearance, representing a continuation of the microblade tradition of Western Beringia (Fig. 5). This line is further developed in artifacts from sites of the Denali complex, which are spread over a wide area and have an age of 12,500–10,000 years ago.

In addition to the Denali complex, two other groups of lithic assemblages are known from sites in northwestern North America (Fig. 5). These should probably be seen as evidence of the existence of other human populations that settled in Eastern Beringia between 14,500 and 10,000 years ago. During this interval the dominant plant communities shifted from mammoth-steppe to mesic shrub tundra, starting in central and southwestern Alaska (14,000–12,900 years ago), and then spreading northwards by about 11,000 years ago.

The occurrence of archeological sites from the beginning of this interval is probably due to the arrival of a new wave of people into Eastern Beringia. The artifact assemblages from the first half of this interval are classified as the Nenana Complex (13,500–13,000 years ago). These sites are quite numerous (e.g., the Dry Creek, Owl Ridge, Moose Creek, and Walker Road sites). The Broken Mammoth and Little John sites should also be included in this list. The main feature of the stone tool industry of the Nenana Complex is the absence of microblades and the presence of teardrop-shaped and triangular spear points (incomplete bifaces) known as Chindadn points.

The duration of the existence of archeological sites from the end of the last glaciation is only about 1000 years, despite the fact that they range from the northeastern Siberia to the Yukon River basin in northwestern North America. Interestingly, such distinctive, short-lived cultural manifestations are not unique. The North American sites associated with the Clovis culture have an even shorter history, falling between 13,000 and 12,700 years ago (Waters and Stafford Jr., 2007). Nevertheless, Clovis artifacts have a very wide spatial distribution across the continent (Waters and Stafford Jr., 2007; Waters et al., 2015).

In both the Nenana and Clovis cases, it appears that the emergence of diagnostic artifacts is more related to changes in adaptations than to the emergence of new population groups, as both Nenana complex and Clovis sites are spread across areas where there

K., van Kolfschoten, T., Bohncke, S., Kosintsev, P. A.,

is or there was a population that did not use Chindadn points, respectively. With regard to sites containing Chindadn points, many of them are characterized by the presence of mammoth remains, and in Western Beringia sites with Chindadn points (Pitulko et al., 2016) appear in the Arctic region just before the demise of the local mammoth population (Pitulko and Nikolskiy, 2012).

The disappearance of Chindadn points was undoubtedly due to environmental factors, including the replacement of the Pleistocene mammoth steppe with tundra landscapes. Mesic shrub tundra would not have been able to sustain populations of megafaunal grazers. At the same time, boreal forests were advancing north and west in Eastern Siberia, reaching their modern limits in some regions by about 9000 years ago. Stands of birch and larch apparently spread beyond their modern limits at the end of the Pleistocene (McDonald et al., 2012; Zimmermann et al., 2017). It is noteworthy that ancient DNA evidence indicates that mammoths and horses persisted in the interior of Alaska until about 10,500 years ago (Haile et al., 2009). This generally confirms the dating of bone residues from these megafauna (Mann et al., 2015).

The people of the Denali and Nenana complexes apparently took part in the settlement of the New World. Presumably they entered no later than 16,000 years ago. Thus far, no archeological sites of this age have been found in southeastern Alaska. In fact, all the Paleolithic archeological sites from Eastern Beringia are in the interior and belong to a clearly expressed adaptation to megafaunal mammal hunting, including mammoths. In this regard, the formation of a maritime economy during the process of settlement of the Americas remains archeologically invisible.

People who settled in Eastern Beringia, in turn, divided (Fig. 3). Nevertheless, the ancient Beringian population maintained genetic integrity for quite a long time in the interior of Alaska (Moreno-Mayar et al., 2018) and did not participate in the further splitting and recombination of the indigenous populations of the Americas. These non-Alaskan native groups eventually divided into northern and southern branches. Human settlement in Arctic North America in the middle Holocene is also associated with a powerful genetic flow of Siberian origin (Gilbert et al., 2008).

When the LGM was over, there is also the possibility of reverse (Alaska to Siberia) human migration from the BLB to Western Beringia. A possible result of such a migration may have been the influx of a wave of population during the end of the Pleistocene. In this scenario, people from both Eastern and Western Beringia shared the toolkit of the Chindadn complex. It has been noted that all sites that yielded Chindadn points in Western Beringia (e.g., Berelekh, Nikita Lake, Achchaghyi-Allaikha) are associated with concentrations of mammoth bone remains (Pitulko et al., 2016). Interestingly, there is genetic evidence that this east-to-west migration pattern was followed by woolly mammoth, as the presence of a strong genetic signal originating from North America has been identified in the genome of mammoths of that lived in Northern Eurasia (Palkopoulou et al., 2013).

In any case, the question of the timing of human entrance into the New World is far from decided. In the non-glaciated regions of the North American continent there are no archeological sites dated beyond 16,000 years ago. This conclusion is the consensus of the archeological community.

An important element of the cultural diversity of the Arctic zone of northwestern North America, but not related to the problem of its settlement, is the presence of sites associated with the Northern Paleo-Indian tradition (Fig. 5), known from the Seward Peninsula in Alaska to the Yukon (e.g., Raven Bluff, Serpentine Hot Springs, Mesa, Irving Sluiceway, etc.). Their distinctive characteristic consists of spear heads with bilaterally processed edges, sometimes with a refined or fluted base similar to the Clovis and Folsom projectile points from unglaciated regions of North America, related to the interval of 12,500 to 11,500 years ago (Fig. 6). However, in Alaska these artifacts are clearly younger than those of the Clovis culture.

It has been shown (Smith and Goebel, 2018) that these diagnostic artifacts appear in northwestern North America as the result of a reverse migration (from south to north) through the ice-free corridor, after the beginning of deglaciation. Their appearance in northwestern North America, among other data on the existence of the Clovis people in the unglaciated regions of the continent (e.g., Waters et al., 2015, 2018) in the period leading up to the opening of the ice-free corridor route, suggests that the infiltration of human groups into glacial North America occurred earlier than 15,000 years ago. However, the specific model of this process remains undeveloped (Potter et al., 2018).

Bison also migrated south to north along the ice-free corridor, after it opened. This is indicated by aDNA evidence from the remains of these animals (Heintzman et al., 2016). This hypothesis is backed by the radiocarbon evidence. There are no dated remains of bison in Alaska during the Late Glacial, but then relatively high numbers are recorded afterward (Mann et al., 2015). Perhaps the same migration corridor served as an avenue of exchange between the Beringian and more southern North American populations of horses and mammoths toward the end of the Pleistocene. This northerly migration might have been driven by environmental changes under the same scenario as in Northern Eurasia (Nikolskiy et al., 2011; McDonald et al., 2012), where the distinctive northward shift of populations of Pleistocene megafauna is associated with the collapse of the steppe-tundra biome at the end of the Pleistocene, and the subsequent transformation into the modern tundra.

On the eve of the end of the land connection between Northern Eurasia and North America (Jakobsson et al., 2017), archeological sites of a different technological tradition spread via the BLB into northwestern North America (Fig. 7). The most important feature of this culture was the microprismatic technique of stone splitting, associated with the use of linear tools, found in caves at Trail Creek (Larsen, 1968) and the Lime Hills (Ackerman, 1996). In some cases, e.g., on Anangula Island in the Aleutians (Coutouly, 2015) it is supplemented by the production of large blades. This technology has also commonly been found in younger sites in Alaska, such as Amakomanak and Panguingue Creek, as well as in younger assemblages from the Anangula site, and in sites along the Pacific Northwest coast, such as Richardson Island, Lille Bay, and Echo Bay (Magne and Fedje, 2007). Despite the lack of direct material evidence, the localization of these technologies along coasts and islands indicates a developed maritime adaptation using boats.

Importance of Dog Sledding

The apparent ability of prehistoric humans to selectively breed dogs for specific traits, combined with the complexity of the sled design known from the Zhokhov site in arctic Siberia (Pitulko and Kasparov, 2017), suggest that these skills have evolved over a period of several thousand years. The development of this mode of transportation was an enormous breakthrough for Arctic peoples. Assuming they traveled in winter, dog-sled transport would have greatly aided the Beringian “stand-still” population in their hunting forays into the adjacent continental regions of either Siberia or Alaska and the Yukon. Even today, the peoples of the North American Arctic find it much easier to travel long distances over the snow in winter than to attempt long journeys over the vegetated, often boggy terrain of summer. Dog sleds may already have been known to people in the American Northwest on the eve of the discovery of the ice-free corridor. Perhaps North American sled dogs descended from animals pulling sleds across the BLB, before its inundation at the end of the Last glaciation (Leathlobhair et al., 2018).

Sled dog breeding is the most important innovation of the Holocene Arctic frontier. This element of adaptation allowed early Holocene hunters in the Siberian Arctic and northwest North America to quickly traverse vast areas, so they could take advantage of shifting resources on the landscape, such as migrating herds of grazers. The distances traveled are indicated by the presence of obsidian tools at the Zhokhov site in northeastern Siberia (Fig. 8) that originated from a source of the obsidian 1500 km away, in the lower Anadyr River (Pitulko et al., 2019).

In northwestern North America, several sources of obsidian have been identified, and these have likewise been distributed widely (Fig. 8). They are localized both in the interior of Eastern Beringia and in the coastal areas of the northwest coast (Potter et al., 2017). It has been shown (Potter et al., 2017) that obsidian from interior Eastern Beringia occurs in archeological sites with ages greater than 13,000 years ago, while the movement of obsidian in the coastal zone is characteristic for younger sites. Indirectly, this fact suggests the absence of migration of human groups along the “coastal route” (Fig. 3) prior to 13,000 years ago.

Fig. 8 Obsidian exchange systems in sub-Arctic and Arctic regions of East Siberia (after Kuzmin, 2019; Pitulko et al., 2019) and Alaska (after Potter et al., 2017) revealed by geochemical signatures found for specific source areas based on data published in: Kuzmin, Y. Early colonization of Beringia and Northern North America: Chronology, routes, and adaptive strategies. *Quaternary International* 444B, 36–55.

Spread of Arctic Peoples in the Late Holocene

By the start of the Holocene, three vast areas of the Arctic remained unpopulated (Fig. 5). These were Scandinavia and the Kola Peninsula in the Old World, the Canadian Arctic in the New World, and Greenland. While the Canadian Arctic and Greenland remained inaccessible to humans for a long time, the settlement of Scandinavia became possible soon after deglaciation (Fig. 9). It is believed that late-Paleolithic peoples whose origins are associated with both Eastern and South-Western Europe were the first post-glacial inhabitants of Scandinavia (Dolukhanov et al., 2002; Zvelebil, 2008).

Fig. 9 Selected Arctic and sub-Arctic archeological sites dated younger than 9000 years ago, and major coastal migrations in the Arctic: (a) postglacial migrations into Scandinavia; (b) Arctic Small Tool tradition spread into Alaska, Canadian Arctic and Greenland at around 5000 years ago; (c) Old Bering Sea culture spread to the west of the Bering Strait about 2000 years ago; (d) Thule migration ~1000 years ago; (e) migration to the west of the Bering Strait contemporary to the Thule migration.

By the middle Holocene, only the Canadian Arctic and Greenland remained unoccupied. Human settlement was hindered by the late deglaciation of the Canadian Arctic islands, around 4000 years ago. At about that time the Paleo-Eskimo culture spread across the Canadian Arctic and Greenland (Fig. 9). It is characterized by the Arctic Small Tool tradition, which is a combination of pre-Dorset local variants in significant parts of the Canadian Arctic and Labrador, the Independence I culture in northern Greenland and High Arctic islands, and Saqqaq culture in Greenland (Friesen and Mason, 2016). Sites of the Denbigh complex in Alaska represent the earliest expression of this cultural tradition. The rate of migration and settlement of these people across the Arctic remains unknown, but it is clear that by 4500 years ago they had occupied all the regions discussed above.

The Palaeo-Eskimo group were the first inhabitants of Greenland, arriving in several waves of migration from about 2500 BC–1400 AD, originating in Alaska or Siberia and crossing the Canadian High Arctic, finishing in Greenland (Sørensen, 2019). The Palaeo-Eskimo people organized themselves in small mobile groups that were able to carry all their goods from place to place using dog sleds. They apparently built no permanent structures but lived in tents. Their great mobility allowed them to exploit food resources at wide-ranging localities through the year. They hunted both marine mammals such as whales, seals and walrus, and terrestrial herbivores, such as caribou and muskox. Their hunting weapons reveal a high level of specialization. For instance, a Paleo-Eskimo site on an island in Disco Bay yielded a suite of hafted artifacts dating back to the Saqqaq Culture (2500–1000 BC) representing one of the most sophisticated prehistoric tool technologies found anywhere in the world. Their hunting tool-kit included nine types of hafted compound tool types, each designed for a specialized use. There were various lances with fore shafts, harpoons with toggling harpoon heads, atlats, three-pronged bird darts, and bows and arrows. In addition to their use of dog sleds over ground, they went to sea in kayaks.

The economy of at least two groups includes a significant marine element, and for pre-Dorset it is assumed that the caribou population was also exploited. It is clear, however, that in order to pursue local caribou populations on the Arctic islands, humans had to have the appropriate technology to provide coastal travel, as well as the skills to exploit marine resources as a back-up option. This allowed the subsequent transition to the maritime adaptation when it became necessary, as evidenced by the Independence and Saqqaq cultures (Grønnow, 2017).

Genetically, these early people of the high arctic were considerably different from both the Native American population who migrated to the Americas at the end of the Pleistocene, and from the bearers of the Thule culture (Inuit people) who spread in the Canadian Arctic and Greenland around 700 years ago. Their closest modern relatives are the inhabitants of Arctic East Siberia—Nganasans, Koryaks and Chukchi (Rasmussen et al., 2010) and the modern inhabitants of the Aleutian Islands (Raghavan et al., 2014). Given the age estimate for the oldest materials in Alaska attributed to Denbigh complex (Giddings, 1964; Harritt, 1998), and the estimated age for the genetic split between Saqqaq and Chukchi (6400–4400 years ago). (Rasmussen et al., 2010), the beginning of the migration across Arctic North America is believed to be ~5500 years ago. The roots of this migration are seen in the material culture of the East Siberian middle Neolithic (Powers and Jordan, 1990; Raghavan et al., 2014), while it remains unclear to what extent it is related to the formation of ASTs.

The latest large-scale migration of Thule culture started from the Bering Strait area about 1000 years ago during the Medieval Warming (Fig. 9). In Canadian Arctic and Greenland, this population replaced the Paleo-Inuit, who lived there for about 4000 years. Contemporary westward migration is less known, but an Eskimo population moved west of the Bering Strait and reached the Kolyma river area (Pitulko and Pavlova, 2016). During the Medieval Warming, the East Siberian arctic coast, which is generally quite barren, became habitable because of the availability of marine resources. In the Canadian Arctic and Greenland, despite the subsequent worsening of conditions, descendants of this population still live today, but the arctic coast of East Siberia soon became abandoned due to the onset of the Little Ice Age, when ice conditions worsened, and the biodiversity of the marine ecosystem decreased.

Abundance of Arctic Marine Resources

An archeological site in the eastern Canadian Arctic (Howse, 2013) reveals a great deal about the abundance of marine food resources and how these were exploited by Arctic Stone Age people in the Canadian High Arctic and adjacent coasts of Greenland. This particular site was occupied by Early Thule Inuit people. They first migrated into the Eastern Arctic from an ancestral homeland somewhere in western Alaska. Their arrival at Skraeling Island, located on the eastern edge of the Canadian High Arctic, near the southeast coast of Ellesmere Island, is one of the earliest known Inuit occupations in this region. A total of 23 Thule Inuit house ruins, numerous tent rings, kayak and umiak supports, and food caches were found on the island. The site was apparently a year-round encampment. Radiocarbon dating of organic artifacts indicates that the island was occupied by these pioneers during the 13th century AD. Their material culture was very similar to that of Alaskan Thule sites, including harpoon head types and a house layout where a separate kitchen was accessed by a tunnel that ran parallel to the main entrance tunnel.

The island was very likely chosen by the Thule people because of its proximity to the North Water Polynya. Polynyas are areas of persistent open water in regions otherwise covered in sea ice for much of the year. For the most part, they tend to be roughly oval or circular in shape, and may be 100 km long, or longer. The water remains open because of oceanic processes that prevent sea ice from forming. Marine mammals, fish, and sea birds congregate at polynyas throughout the winter. Year-round access to these ice-free waters would have made Skraeling Island an attractive location to Arctic peoples, because important marine resources were readily available year-round. Large populations of beluga, narwhal, bowhead whale, and walrus are found there today during the summer

months, and smaller numbers of these animals spend the winter there. Polar bears are present year-round and abundant along the edge of the polynya throughout the winter, since they hunt seals from the edge of the ice. The seal fauna found in the polynya include ringed seal and bearded seal, which are also year-round residents. Harp seals pass through the region during their summer migration. So even though the island itself experiences extremely cold climate and is essentially polar desert, the paucity of terrestrial game animals was of little concern to these highly adapted maritime people. In fact, it appears that they harvested both abundant and diverse foods from the sea.

The bones of the following species of birds, marine mammals and terrestrial mammals have been identified from the Early Thule sites on Skraeling Island: goose, eider, common raven, arctic hare, narwhal, beluga whale, bowhead whale, arctic fox, polar bear, walrus, bearded seal, gray seal, ringed seal, harbor seal, harp seal, caribou and muskox. Seal bones dominated the faunal samples, contributing more than two-thirds of the identified mammal remains. Dog bones were also frequently encountered in the excavations, testimony to the use of dog sleds.

The Early Thule people not only relied on marine mammals for their food, they also made use of some of their bones as building materials. The inhabitants of the site on Skraeling Island used the skulls and other bones of whales and walrus to form most of their house structures. One house had seven walrus skulls built into a wall. The gaps between bones were likely filled in with blocks of turf. Thus, it appears that the Early Thule Inuit lived in robust, well-insulated houses during the winter, and that they slept in tents during warm weather, based on the presence of several tent rings on the island.

Metallurgy in the Arctic

The cultures of the Arctic Stone Age, long before the advent of metallurgy, remained stable for millennia. This does not imply that Arctic cultures stagnated. On the contrary, they were very dynamic, but they achieved the right balance between technology and habitat. Metal working in the New World began with cold hammering of native copper at about 6000 years ago, in the Great Lakes region of the North America well south of the Arctic and with no indication for smelting of raw materials and casting technology (Bebber and Eren, 2018). No evidence for bronze casting exists in the New World Arctic, contrary to the arctic Eurasia. The earliest and only known evidence for iron working discovered in this region comes from Canadian Arctic and dates about 1000 years ago (Sutherland et al., 2015).

The use of metal products in the Arctic Stone Age cultures was not critically important. Thus, in Thule culture, a significant amount of iron products (including meteoritic iron) is known, but such products are mainly a result of long-distance exchange with Siberian territories (Cooper et al., 2016). There is no single element in Thule material culture which could have not been made simply by using stone tools. In similar fashion, bone tools apparently fulfilled all the needs of the people of the Old Bering Sea culture, even though iron in small quantities was available to them.

It is clear from this that metal working technology was not a significant aspect of ancient Arctic peoples. Metal tools were not critically important to these people. Their production is very labor-intensive, and it did not lend itself to production by the small groups of people that made up hunter-gatherer bands. In addition, such technological knowledge is more-or-less useless in regions that lack the raw materials for metallurgy. So, while metal tools were desirable, they never became a critical element of culture and survival technology. Arctic exchange systems, including ultra-long-distance, existed at least 5000 to 6000 years before the advent of metals. These transactions were much more effective in terms of the use of time, which in the Arctic is limited to the short summer-spring season.

Concluding Comments

The human occupation of the Arctic during and after the Last glaciation staggers the imagination. As mentioned above, *Homo sapiens* evolved in tropical Africa, and our physiological and morphological adaptations have changed little through the Late Quaternary. But the undeniable fact is that humans did not just survive in the Arctic with just their Stone Age technology, they actually thrived there. Certain technological innovations were critical to this success. The human body, exposed to the elements, starts to shiver at 35.5 °C, and we enter hypothermia when our core body temperature falls to 35 °C. So, the first vital piece of technology was the invention of tailored clothing to insulate their tropically adapted bodies from the bitter Arctic cold. Since they were living in a treeless landscape, these first Arctic inhabitants managed to survive winter nights by burning the fatty marrow inside large mammal bones. Their stone tool kit was sufficiently lightweight and compact to allow them to take it with them on long trips, yet it included highly sophisticated weapons that brought down large animals. In short, these Stone-Age peoples of the Arctic are a testimonial to human ingenuity.

We are only now beginning to understand the prehistoric occupation of Arctic regions. The extraction and identification of Ancient DNA from fossil human bones and teeth represents a vital breakthrough in our understanding of the genetic relationships of the First Americans. However, the Arctic is one of the most remote regions on Earth. Access to potential archeological sites is costly, difficult, and restricted to a few weeks of the summer. For these reasons, many of the Arctic territories remain archeologically unexplored, and a significant number of research questions remain largely open.

Abstract

Although much of the Arctic remains pristine, the developed countries of the world have used the Arctic tundra as a dumping ground, for nuclear testing, and an industrial site. Since the 20th century, Arctic regions have been exploited for mineral and petroleum resources with a mixed level of concern for environment (some in USA and Canada, very little in Russia). The remoteness of the Arctic has made it a target for extensive Russian nuclear testing (Novaya Zemlya), and proposed nuclear engineering (NW Alaska). The warming of the Arctic climate, though not originating from Arctic sources, is melting the sea ice cover, melting the permafrost, and changing tundra ecosystems. Ironically, anthropogenic warming is even now facilitating further human exploitation of the High Arctic for its fossil fuel resources, navigational short-cuts, and previously unobtainable fish stocks. These new incursions into the Arctic may well drive a number of marine mammals and other vertebrate species to extinction, unless strong conservation initiatives are put in place immediately.

Introduction

The arctic tundra is not a frozen wasteland of monotonous mosses and lichens, barely clinging to life. In fact, the tundra is as diverse in vegetation communities as the boreal forest or temperate grassland biomes to the south. Tundra covers about 360,000 km² in Alaska, 2,480,000 km² in Canada, 2,167,000 km² in Greenland and Iceland, and 2,560,000 km² in Russia (Bliss and Matveyeva, 1992). The simplest definition of arctic tundra is the land beyond the northern limit of trees, but there are extensive regions where patches of tundra extend south into the boreal forest. This forest-tundra ecosystem is much more extensive in northern Siberia than in North America.

For the purposes of this review it is convenient to divide the biome into high and low arctic ecosystems (Fig. 1). The High Arctic, also known as polar desert, occurs in the far north, such as the Canadian Arctic Archipelago, northern Greenland, and the islands north of Siberia. Here the vegetation cover is generally sparse, and the plant diversity is quite low. The climate is extremely cold, with mean July temperatures from 1 °C to 4 °C and mean January temperatures in the –20 °C to –40 °C range. Mean annual temperatures are well below freezing, from about –6 °C to –15 °C. Mean annual precipitation is very low, ranging from about 60–400 mm, with most of this falling as snow. The High Arctic is a frigid desert. The low arctic tundra is much more floristically diverse and extensive in area. Depending on latitude, slope, aspect, and available moisture, the vegetation ranges from tall shrubs to prostrate herbs, lichens, and mosses. Mean July temperatures in the Low Arctic range from 4 °C to 12 °C; mean January temperatures range from about –15 °C in arctic Scandinavia to –50 °C in the coldest parts of north-eastern Siberia. Mean annual temperatures range from about –1 °C to –15 °C. Mean annual precipitation ranges from about 120–550 mm. Because the mean annual air temperatures of all these tundra regions are below freezing, the entire region, both low- and high-arctic, have permanently frozen soils, or permafrost. The upper layers of these soils, the top 0.4–4 m, generally thaw in summer, forming an active layer in which plants can take root, and draw moisture and nutrients. The soil remains frozen below this active layer, often to depths of hundreds of meters. The coldest parts of north-eastern Siberia have soils frozen to depths exceeding 1500 m.

Fig. 1 Map of the northern high latitudes, showing the High Arctic and Low Arctic regions.

Tundra plants are highly adapted to survive the very short growing season, low summer temperatures, extremely cold winters, and lack of moisture. Many tundra plants are perennials. This life strategy allows them time to slowly accumulate the metabolic energy needed to set seeds, a process that may take several summers. Likewise many tundra insects live multiple years in order to accumulate enough energy to reproduce. There are very few year-round resident vertebrates in the Arctic. Most birds are only summer visitors, taking advantage of the rapid growth of plants in the continuous daylight, and the lack of predators they face in lower latitudes, to quickly raise a brood of chicks in the short, intense Arctic summer. The few resident birds, such as ptarmigan, burrow under the snow in winter, thus avoiding the deathly cold air temperatures at the surface. These birds build up as much fat as possible in the summer, and survive the winter by a combination of burning fat reserves and foraging on dwarf willow and birch shrubs beneath the snow. There are 39 resident terrestrial mammals in the Arctic, including 21 species found in both the Low and High Arctic, 17 species found only in the Low Arctic, and only one species found only in the High Arctic (Table 1).

Threats to the High Arctic

Declining Sea Ice (Global Warming)

Sea ice forms in the Arctic Ocean and adjacent seas from autumn to early summer. Prior to the 1980s–90s, annual layers of sea ice would build up for several years, thickening the ice pack considerably. This pack ice provides a stable platform from which polar

Tundra shrew	<i>Sorex tundrensis</i>	Low and High Arctic	Least concern

bears, arctic foxes and walruses hunt. However, the extent and thickness of sea ice has been decreasing rapidly in recent years, because multiyear ice has almost disappeared from Arctic waters. In recent decades, rapid warming of Arctic climates has seen a major sea ice loss along the coasts of arctic Russia, Canada, and Alaska. Sea ice cover reached a record low in 2012, and more than 2 million km² has been lost since 2000. This represents a loss of 49% of the extent of sea ice cover observed from 1979 to 2000 (Fig. 2). Recent forecasts by NOAA (2018) suggest that Arctic sea ice cover is shrinking by 12.8% per decade. This indicates the very likely disappearance of Arctic sea ice cover during the first half of the 21st century (Fig. 3). So it appears to be a question of *when* Arctic sea ice cover is lost, not *whether* it will be lost. The loss of sea ice cover creates a positive feedback loop for general atmospheric warming of the Arctic region. The white surface of sea ice reflects a large proportion of solar radiation back out to space. That white surface turns to a very dark surface when sea ice gives way to open water. The open ocean absorbs a great deal of solar energy, which in turn warms the entire Arctic region. In 2017, Arctic sea surface temperature was 4 °C warmer than the 1982–2010 average.

Biological Impacts

Since 1981, the loss of summer sea ice cover has been 1.6 million km², an area roughly 40% of the size of the European Union countries. Thus this sea ice cover has become unavailable to arctic marine mammals by the end of summer. The loss of sea ice and associated regional warming are exerting environmental pressure on the regional biota, both in the Arctic Ocean, and in the near-shore environments on land. Post et al. (2013) reviewed the biological impacts of sea ice reduction, showing that sea ice loss represents a huge habitat reduction for sea-ice algae and phytoplankton. These organisms represent 57% of the primary

Fig. 2 Map of the northern high latitudes, showing the extent of September sea ice in 2018, 2012, and 1984. Data from National Snow and Ice Data Center.

productivity in the Arctic Ocean. Organic detritus frozen into the pack ice is released into the water column as the ice melts in spring. This pulse of organic material is used by phytoplankton and zooplankton to facilitate their growth and reproduction as summer comes on. This burst of biological productivity makes its way up the food chain. The phytoplankton feed the zooplankton, which in turn feed crustaceans and small fish. Cod and capelin feed on smaller fish. Beluga whales feed on a wide variety of bottom-dwelling fish, squid, crabs, and other invertebrates. Walrus feed almost exclusively on mollusks, but also take other marine invertebrates. They use the pack ice as a platform for pupping and sea-floor foraging, as do Arctic seals. Walrus use sea ice for molting, mating, resting between hunts for food, and walrus mothers nurse their young on pack ice. Pacific walrus females and their young spend the summer on sea ice in the Chukchi Sea between Alaska and Siberia. This region could be free of summer sea ice cover by 2060 or sooner, according to the U.S. Fish and Wildlife Service.

The Arctic supports a particularly rich diversity of seal species, including ribbon seals, bearded seals, ringed seals, spotted seals, harp seals, and hooded seals. Because of the disappearing sea ice, several of these species are under consideration by the United States government for listing under the Endangered Species Act. The most threatened species is the ribbon seal, which lives on the outermost edges of sea ice, near deep water. These are most likely to be affected by loss of habitat as sea ice continues to shrink. Polar bears spend the winter on the pack ice, hunting seals as they come up for air in small openings in the ice. Arctic foxes often follow behind the bears, scavenging seal carcasses after the bears have abandoned them.

Without sea ice cover, the whole process described above will cease to exist. The volume of organic detritus will be severely decreased, greatly curtailing the annual phytoplankton productivity bloom. Phytoplankton are primary producers of this marine

Fig. 3 Graph showing the decline in September Arctic sea ice from 1979 to 2018. Data from National Snow and Ice Data Center.

ecosystem. Without sufficient primary productivity, all the consumers, from the zooplankton to the marine mammals, suffer from a lack of food. The lack of sea ice cover is already shortening the polar bears' hunting season, as the bears must now wait several extra weeks for the sea ice to form in the autumn. If the sea ice cover disappears, the polar bear is likely headed for extinction. Walrus are also being forced to haul out onto land to bear their pups and rest, increasing over-crowding of walrus on beaches, facilitating disease transmission within populations.

Oil and Gas Development

As the extent and thickness of sea ice declines in the Arctic Ocean, both Russia and the United States have been exploring the possibilities of oil and gas well development in the High Arctic, including drilling in the Arctic Ocean. Only about one-third of the Arctic is covered by land; another third consists of the offshore continental shelf, with waters generally less than 500 m deep. The remaining third comprises deep ocean waters. Most of the Arctic waters are currently ice-covered for most of the year. But as we have seen, Arctic sea ice cover has been receding in recent years. The Arctic region contains portions of six countries that have Arctic shorelines: Canada, Greenland, Iceland, Norway, Russia, and the United States. Finland and Sweden do not border on the Arctic Ocean and are the only Arctic countries without jurisdictional claims in the Arctic Ocean and adjacent seas. An assessment of oil and gas potential in the Arctic by the US Geological Survey concluded that 770–2990 trillion cubic feet of natural gas reserves lie north of the Arctic Circle, mostly in Russia (Gautier, 2011). Overall, the Arctic is estimated to contain between 44 and 157 billion barrels of recoverable oil. Approximately 84% of these fossil fuel resources are expected to be found offshore, so governments, government-owned oil and gas companies, and private companies are now considering Arctic Ocean drilling. The burning of the fossil fuels extracted in these enterprises will exacerbate global warming, which in turn will melt more Arctic sea ice.

In fact, oil drilling in the Arctic Ocean is just about to begin. In October 2018, U.S. Interior Department officials announced their approval of a plan to drill for oil 6 miles off the northern Alaskan coast in the shallow waters of the Beaufort Sea. Hilcorp, based in Houston, plans to build a nine-acre gravel island about 20 miles east of Prudhoe Bay, not far from the Arctic National Wildlife Refuge. Such activities will alter habitats and disturb marine life. Of particular note is the disturbance of the region's rich marine mammal fauna, as discussed by Huntington (2009). He reckons that offshore oil and gas facilities will disturb marine mammals through noise from seismic surveys, shipping, and drilling. Chronic pollution, in addition to potential oil spills, will contaminate Arctic waters, producing cumulative impacts that will extend beyond the continental shelf regions where these activities will take place. Bowhead whales have already shifted migratory routes in the Beaufort Sea to avoid noise from oil and gas development activities, such as drilling. If preferred habitats for breeding, calving, feeding and migration are disturbed over large areas, the overall fitness of marine mammal populations in the Arctic Ocean will decline.

Navigation of High Arctic Waters

One of the greatest ecological threats of declining sea ice is the increased access to the Arctic Ocean this will give to non-native peoples. European explorers started looking for a Northwest Passage through Arctic waters as far back as the late 15th century

with the voyages of John and Sebastian Cabot. The waters of the Canadian Arctic Archipelago were clogged with drifting sea ice during the summers of the next several centuries, and only in the 20th century was a route successfully navigated. In 2013, a large freighter navigated the Northwest Passage. In November 2013, the Russian company Gazprom made the first ever delivery of liquefied natural gas through the Arctic north-east route, sailing from Norway east to Japan. Large volumes of commercial shipping via the Arctic are probably 10 years away, but this appears to be another inevitable outcome of warming in the Arctic.

Black carbon (BC) is a particulate matter produced by ships through incomplete burning of diesel fuel. International shipping emits between 71,000 and 160,000 metric tons of BC annually. In the Arctic region in 2004, approx. 609 tons of black carbon was released. These black particles fall on the snow and ice surfaces of arctic sea ice and lands, where they absorb solar radiation and cause melting (Fig. 4). Although the amount of BC is currently low, as shipping traffic increases in the Arctic, the effects of BC described above means that even small amounts could have a potentially disproportionate impact on ice melt and warming of the region. A recent study found that the heaviest CO₂ and BC emissions were found in the Bering Sea region, around Iceland, along the Norwegian coast and in the Barents Sea.

The Arctic marine environment is highly sensitive to impacts from increased shipping, as discussed by Eger (2018). A large number of marine species travel throughout the Arctic to feed, mate, give birth, take care of their young and molt. These aspects of their life cycles will be exposed to various kinds of disturbances from shipping. Toxic substances are released as emissions to the air or as discharges to the water, including the accidental releases of oil or hazardous cargo. Disruption of marine life is caused by ship noise and by collisions. In the long term, ships are likely to accidentally introduce invasive marine species into Arctic waters as they have elsewhere. There are 280 species of birds, marine mammals and fish known to migrate through Arctic waters, and around 450 species are known to breed in Arctic waters or along Arctic shores. Many species that undertake annual migrations appear to use seasonal changes in oceanic environmental conditions as cues. Unfortunately, the migration routes used by mammals and birds correspond closely with the main shipping routes into and out of the Arctic. Presently, there is limited overlap between marine fauna and ships during the spring, as all shipping activity typically occurs later in the spring than the animal migrations. This situation may change if the date of ice break up moves earlier in the year. In the autumn there is a greater probability of interaction between ships and migrating marine species, as both are leaving the Arctic in advance of the formation of pack ice. The spring migration routes of marine mammals and birds are especially sensitive to disturbance. The brief feeding seasons of these animals mean that if feeding is disrupted, the animal may not survive the next winter. These unique characteristics make Arctic species vulnerable to disturbances caused by shipping activities. If large ships rely on ice-breakers to open shipping lanes, then the ice-breaking ships also add to wildlife disturbances. For instance, they are known to disrupt birthing of seal pups on the ice. The regulation of tanker traffic, such as that in the Barents Sea, will require intergovernmental cooperation between Norway and Russia.

Pollution

Creeping in from the south, air pollution has been acidifying arctic lakes in recent decades, even though the source of pollution is thousands of km to the south. More than 20 years ago, Douglas et al. (1994) found that the characteristic diatom floras of lakes and ponds in the Canadian High Arctic had changed dramatically in the previous two centuries. Such changes are probably linked to multiple factors, including air pollution, warming temperatures, and increased levels of ultra-violet radiation. Persistent organic

Fig. 5 Sources of persistent organic pollutants and mercury that make their way to the Arctic Ocean. After figure by the Norwegian Polar Institute.

pollutants (POPs) are being transported into the High Arctic from sources well to the south (Fig. 5). The Norwegian Polar Institute (2018) reports that traces of these and other pollutants are found throughout the arctic environment, including pollutants in the air, soil, snow, sea ice and glaciers, seawater and fresh water, birds, mammals and people. Unfortunately, the Arctic acts as an indicator region for known and new pollutants. If a pollutant is found in the Arctic, it is an indication that the substance has been transported a long distance, is poorly degradable and is taken up in organisms.

A number of POP compounds have made their way from the mid-latitudes to Arctic waters (Fig. 5). PCB is polychlorinated biphenyl, a group of organochloride compounds that were widely used as dielectric and coolant fluids in electrical equipment until they were banned by many governments in the late 1970s and 1980s. This group of toxic compounds persists today in the Arctic. PCB values from air measurements at a research station in Svalbard show higher levels than at corresponding stations in Canada, suggesting that the European Arctic receives more PCB than the North American Arctic. The PCB levels in polar bears in Svalbard are two to six times higher than in polar bears from North America. Polar bear tissues have also been found to contain high levels of certain kinds of brominated flame retardants. Scientists have also found a number of newly developed chemical compounds that are polluting the Arctic, such as various kinds of brominated and fluorinated substances. Another POP is Hexachlorocyclohexane, or HCH. This is another organochloride compound that was used as a pesticide in the 1960s and 1970s, but persists in the environment throughout the world's oceans. Chlordane is an agricultural insecticide that is highly toxic to aquatic organisms, both freshwater and marine. It washes from farmer's fields into waterways and eventually makes its way to the world's oceans. Once there, it takes a very long time to break down. It binds strongly to ocean sediments and accumulates rapidly in the tissues of many aquatic species, working its way up the food chain. Even though the import and export of Chlordane has been banned by international conventions, it has become widely dispersed and has been found in arctic air, and water, where it threatens the health of fish, marine mammals and humans.

In addition to these exotic pollutants, sources of pollution closer to the target areas are also being produced in the European Arctic and subarctic. These include dioxins from smelters in Norway, heavy metals from industrial activities in the Kola Peninsula and the Norilsk industrial complex in northwest Russia. Mining takes place in several parts of the Arctic, such as the Pechenga-Nikkeli district of Svalbard, and in parts of Siberia, and it represents a local source for contaminants such as PAH, heavy metals and PCBs. The contaminants are transported to the Arctic by rivers, winds and ocean currents, and new substances are constantly appearing.

Unfortunately, dioxins, polychlorinated biphenyl (PCB), other organic compounds, and heavy metals such as mercury tend to accumulate in the tissues of vertebrates. Because the polar seas are the recipients of these pollutants, the marine animal life of the region has been poisoned by them. These pollutants tend to accumulate in the fatty tissues of marine mammals, so their concentrations become far higher than those found in organisms lower down the food chain. A summary of the accumulation of organic pollutants and mercury in Canadian arctic vertebrates by Braune et al. (2005) showed that the concentrations of PCBs in zooplankton range from about 15–55 ng per gram of dry weight. Beluga whales eat fish that have eaten other fish and zooplankton. The concentrations of PCBs in beluga blubber in the Canadian arctic range from about 3000 to 5000 ng per gram of blubber, a concentration about 150 times that found in zooplankton. Polar bears eat mainly ringed seals in these waters. The seals eat fish that have eaten other fish and zooplankton. The concentration of PCBs in polar bear fat is about 1000–2500 ng per gram.

Following the mercury trail

According to a recent study (Lamborg et al., 2014), the total anthropogenic mercury released into the ocean is estimated to be as much as 80,000 metric tons. Two-thirds of this mercury is found in shallow marine waters (less than 1000 m) where many fish live. Mercury becomes bio-accumulated in marine food chains in the form of highly toxic methyl mercury which can cause health risks to marine mammals and humans. Obrist et al. (2017) studied the sources of mercury in Arctic Ocean waters. They found that most of the mercury (about 70%) in the interior Arctic tundra is derived from gaseous elemental mercury deposition, with only minor contributions from the deposition of mercury coming from rain or snow. They found that deposition of elemental mercury, the form present throughout the global atmosphere, occurs throughout the year in the Arctic, and that its concentration on arctic tundra is enhanced in summer through the uptake of mercury by vegetation. Plant uptake of gaseous mercury leads to soil concentrations greatly exceeding the levels found in temperate soils. The authors suggest that high tundra soil mercury concentrations might also explain why Arctic rivers annually transport large amounts of mercury to the Arctic Ocean.

Wang et al. (2018) attempted to track mercury once it enters the Arctic Ocean. Mercury is a contaminant of major concern in Arctic marine ecosystems. Decades of observations in marine biota from across the Canadian Arctic show generally higher mercury concentrations in the west than in the east. Methyl-mercury (MeHg) is the compound that accumulates and biomagnifies in marine biota. Wang et al. (2018) performed a series of high-resolution vertical profiles of total mercury and methyl-mercury in seawater along a transect from the Canada Basin, across the Canadian Arctic Archipelago and Baffin Bay, and into the Labrador Sea. They found that total mercury concentrations are lower in the western Arctic, in contrast to the pattern of the mercury concentrations in marine organisms, which are higher in the western Arctic and decrease eastward (Fig. 6). However, they also found that methyl-mercury shows distinctive maximum concentrations at depths of 100–300 m in the Arctic Ocean, with its peak concentration in the west, and decreasing eastwards. In these water depths, the maximum concentration of methyl-mercury lies within the habitat of zooplankton and other lower trophic-level biota. These small organisms take up methyl-mercury in their tissues, and are then eaten by fish, which are eaten by seals, that are eaten by polar bears. Thus the biological uptake of subsurface methyl-mercury at the bottom of the food chain leads to subsequent biomagnification in fish, marine mammals, and humans. This explains the east-west biotic mercury concentration gradient.

Fig. 6 Mercury concentration levels in two zooplankton taxa (*Calanus* and *Themisto*), ringed seals, and polar bears, across the Canadian High Arctic region. Data from Wang, K., Munson, K. M., Beupr -Laperri re, A., Mucci, A., Macdonald, R.W. et al. (2018). Threats to the Low Arctic

Population Pressure

About 4 million people live in the Arctic. Only a few thousand live in the High Arctic. The rest live in the Low Arctic, almost half living in Arctic Russia (Fig. 7). Because Arctic Russia, Alaska, Canada and Greenland are such large regions, the population density remains very low (less than 50 people per 100 km²) in these regions. Arctic Scandinavia has higher population densities. Farming is virtually impossible in the Arctic and the traditional hunter-gatherer lifestyle of the native Arctic peoples has diminished greatly since the second half of the 20th century, so most Arctic residents live in towns and villages. For the most part, these communities do not generate potent environmental impacts on surrounding landscapes, although home heating oil and diesel-powered vehicles contribute to the black carbon problem. Most of the serious environmental impacts come from regional industrial sources, such as oil wells and pipelines, gold mines and other mineral extraction facilities, and ore smelting plants in Arctic Russia.

Chemical Pollution and Vehicular Damage

The most polluted arctic region is the Kola Peninsula of northwest Russia, where mining operations and emissions from nickel smelters in and around the city of Norilsk emit up to 2460 tons of nickel, 1600 tons of copper and 500,000 metric tons of sulfur-dioxide per year (Moiseenko and Kudryavtseva, 2001). Copper and nickel concentrations in soil and water are at toxic levels within a 30 km radius of the city. These toxic heavy metals, and especially sulfates, have been found in air samples in the atmosphere surrounding Norilsk. Simonenkov et al. (2016) found that at a distance of 92 km from the source, air samples contained pollution dominated by sulfates, followed by chlorine, bromine, lead, nickel, calcium, iron, potassium, sodium, and ammonium.

Fig. 7 Population centers along Arctic coastlines. NOAA Arctic Program (public domain).

Tundra vegetation and soils are particularly vulnerable to chemical pollution. Toxic chemicals stay in the shallow active layer of soils. The permafrost boundary prevents chemicals from moving down to deeper layers. Near-freezing soil temperatures in the active layer slow the breakdown of pollutants, keeping soils toxic for decades or centuries after the initial contamination. As discussed above, atmospheric circulation brings air pollution from lower latitudes, and the pollutants tend to concentrate in polar regions. Tundra vegetation is also particularly vulnerable to physical disturbances. Arctic plants recover with difficulty after disturbances, because they grow very slowly, and may only set seed every few years. Heavy vehicles driven over the tundra degrade the permafrost, leading to the melting of frozen ground (thermokarst). Deep scars from this melting persist for many decades. Roads, buildings and other structures must be insulated from the permafrost, or the heat they generate causes the ground beneath to melt.

Climate Change and Permafrost Melt

As arctic temperatures climb with global warming, the southern edge of the permafrost zone is retreating northward. The permafrost is rapidly receding, especially in the European part of the Russian Arctic. Between 1995 and 2005, the southern boundary of the regions with continuous permafrost (areas where at least 90% of the landscape is underlain by permafrost) migrated north by up to 50 km (Alfred Wegener Institute for Polar and Marine Research, 2018). In areas with discontinuous permafrost (areas where 10–90% of the land is underlain by permafrost), the boundary receded by as much as 80 km. This retreat of the permafrost zone has impacts on natural systems, because tundra vegetation evolved to grow in the shallow active zone above permafrost. As permafrost disappears, other plants, adapted to unfrozen soil regimes, can out-compete the native tundra vegetation.

Niittynen et al. (2018) performed a modeling assessment of the effects of both increased mean annual temperatures and decreased snow cover on the diversity of tundra plants for a region of northern Scandinavia (Fig. 8). They ran their model on 273 vascular plant, moss and lichen species in 1200 study sites spanning a wide range of environmental conditions. One of their model runs was based on a climate change impact model in which temperature increases are likely not to exceed 2 °C above the long-term average. They found that higher temperatures increased overall species richness and caused only one species to lose a suitable habitat. In contrast, a shorter winter snow cover duration (SCD) led to accelerated rates of species' local extinctions after a tipping point of 20–30% SCD decrease (Fig. 8). When a decrease in SCD reached 40%, plant and moss species extinctions exceeded 15%. Lichen species were more resistant to snow cover loss.

Fossil Fuels Development

Oil and gas extraction began in the Arctic during the 20th century. Major oil and gas deposits were found in arctic Alaska in the 1950s and 1960s. The Alaskan Prudhoe Bay oil field came online in 1977; peak production was 2 million barrels of oil per day in 1988. By 2017, the Prudhoe oil field produced only 280,000 barrels per day, a drop of 86% from 1977 levels. However, increases at other North Slope oil fields boosted the flow of oil through the Trans-Alaska Pipeline to an average of 526,000 barrels per day in 2017. The crude oil is transported 1290 km south to the port of Valdez via the trans-Alaska pipeline. The pipeline is above ground

Fig. 8 Predicted extinction rates of vascular plant, moss and lichen species for a suite of test sites in northernmost Scandinavia, versus changing snow cover duration, given greenhouse gas emission scenario RCP 4.5 (increase of mean temperatures ≤ 2 °C). Data from Niittynen, P., Heikkinen, R.K., Luoto, M. (2018). Snow cover is a neglected driver of Arctic biodiversity loss. *Nature Climate Change* 8, 997–1001.

over the tundra, on insulated stilts that keep the permafrost from melting. So far, 17 billion barrels of oil have gone down the pipeline since 1977. These have been transported by more than 12,000 oil tankers for transport by sea around the world. One of these tankers, the *Exxon Valdez* ran aground in 1989, spilling 53 million gallons in Prince William Sound. The ecological devastation of that oil spill has not fully dissipated.

The US Congress established the Arctic National Wildlife Refuge (ANWR) in 1980. Congress deferred a decision regarding future management of the 1.5-million-acre coastal plain in recognition of area's potentially enormous oil and gas resources and its importance as wildlife habitat. Numerous test wells have been drilled and oil fields discovered near ANWR. In 2017 the Trump Administration announced its intention to open ANWR to oil and gas development. This led to a new assessment of oil and gas reserves in Arctic Alaska by the federal government. In 2018 the US Department of the Interior announced that Alaska's combined onshore and offshore fossil fuel reserves collectively hold about 739 billion gallons (2.8 trillion liters) of oil and more than 50 trillion cubic feet (1.4 trillion cubic meters) of natural gas. In August 2018, a Department of Interior official said the agency is moving forward to open a portion of the Alaska National Wildlife Refuge (ANWR) to oil and natural gas leasing in 2019, and predicted that a lease sale scheduled for the region will attract significant interest from producers. The Bureau of Ocean Energy Management revised the estimated recoverable petroleum resources in the Beaufort Sea Outer Continental Shelf Planning Area to 374 billion gallons of oil and 27.7 trillion cubic feet (780 billion cubic meters) of natural gas.

ANWR provides habitat for millions of migratory birds, caribou, polar bear, grizzly and black bears, wolves, Dall sheep, musk-oxen, arctic and red foxes, wolverines. The proposed oil and gas development would occur on the 607,000 ha coastal plain. This area is the most sensitive for wildlife in the entire refuge and any habitat loss that occurs here will impact the entire Arctic Refuge.

There is a particular concern about the effects of oil and gas production on polar bears. Disturbance of female polar bears while denning could cause them to abandon cubs. Damage or destruction of essential polar bear habitat (e.g., feeding, breeding, and especially denning areas) may be caused by dumping, dredging, drilling and construction of platforms, pipelines, roads, and support facilities. Attraction of the bears to industrial areas may lead to habituation to humans, forcing the need for increased control actions, including the trapping or shooting of habituated bears. Harassment (disturbance) by aircraft, ships and other vehicles will cause the bears stress, both when they are on land, and when they are at sea in the winter. Finally, the offshore oil and gas facilities will have detrimental effects on the polar bear's main source of food, ringed seals, due to impacts of oil, noise and chemical contaminants. Marine mammals (whales, seals, and walrus) will very likely be affected by offshore drilling in the Beaufort Sea.

Oil production in Arctic Eurasia focuses on western Siberia, where 68% of Russian gas and oil extraction take place. The biggest of these are in the Ob River basin, where 300 oil fields have pumped 65 billion barrels of oil since 1965, four times the quantity of oil pumped through Trans-Alaska pipeline. The Russian government estimates that at least 5% of the oil recovered from western Siberian wells has been spilled on the tundra surface since the 1960s. This amounts to 3 billion barrels of oil spilled in the Ob River and adjacent basins. A report by [Salmina \(2010\)](#), a regional ecologist, states that there is no fish life in the Ob, Nadym, Pur, and Sob rivers because of pollution from oil production. The pollution is not limited just to the oil itself. Salts and heavy metals are in the brine that comes to the surface with oil from wells. These by-products are dumped on the land. The Russian oil industry tacitly acknowledged the level of water pollution in oil field regions when it installed water purification plants on-site, as the local water is unsafe to drink.

Russian oil drilling on the continental shelf regions of the Arctic Ocean has also accelerated recently. In April 2017, the Russian state-controlled oil giant Rosneft started drilling the northernmost well on the Russian Arctic shelf in the Laptev Sea ([Paraskova, 2017](#)). The oil firm said that recoverable reserves at the field exceed 24.6 billion gallons. Geological data point to reserves at the field at 92 billion gallons. The Prirazlomnoye oil field in the Pechora Sea started pumping oil in late 2013. The field is estimated to hold 21.5 billion gallons of oil, with annual production averaging 1.7 billion gallons at full capacity.

Fisheries

Until now, commercial fishing has been quite limited in the Arctic Ocean. Baffin Bay and the Barents Sea have had the most commercial fishing thus far, along with the sub-arctic waters of the Bering and Norwegian seas. Sea-ice declines will allow commercial fisheries to expand into the Arctic in the coming decades. This will diminish fish stocks in the Arctic Ocean. As has been seen in the North Atlantic and other over-fished regions, diminished stocks of predatory fish such as cod alter food-web dynamics. Such changes in food supply will also add extra stress to fish-feeding marine mammals in Arctic waters, such as some whales, seals and sea lions.

Nuclear Testing

From 1954 to 1990, the Russian islands of Novaya Zemlya were used extensively for both above- and below-ground nuclear weapons testing. The indigenous Nenets population was forcibly resettled and the islands were divided into different testing zones. Novaya Zemlya was the site of 130 nuclear detonations, including the "Tsar Bomba," the biggest nuclear device ever detonated (50 megatons) ([Nuclear Risks, 2018](#)). In addition to bomb testing, the Russian government used these islands to dump nuclear waste. The cores of 13 broken-down nuclear reactors, along with spent fuel from nuclear submarines, were dumped along the coast of Novaya Zemlya and into the Barents and Kara seas. Two of the most contaminated sites on Novaya Zemlya are the Abrosimov and Stepovogo Fjords in the southern part of the island.

The Russians were not the only ones who considered their Arctic regions suitable places for nuclear weapons testing. In 1957 the US Atomic Energy Commission set up a project to use hydrogen bombs to create an ocean harbor in arctic Alaska, as a peacetime use of nuclear weapons. They chose a site in northwestern Alaska, at Cape Thompson. The story of this project is told in "The Firecrackers Boys" by O'Neil (1995). The region was considered uninhabited by the AEC, and it was well away from population centers, so the resulting radiation would not poison the population. As it turned out, quite a number of Inupiat Eskimo families did live and hunt at Cape Thompson. They had no need of a new harbor in this region, as the waters along the cape were blocked by sea ice for 8–9 months of the year. However, the project got the support of the newly formed state government in Alaska. As soon as the plans were made public, opposition came from the tiny Inupiat Eskimo village of Point Hope, from the scientists engaged in environmental studies under AEC contract, and a from handful of conservationists.

Environmental studies commissioned by the AEC suggested that radioactive particles from the blast would land on lichens, be eaten by caribou, and end up in people (for whom caribou was a primary food source). The people of Point Hope wrote to President Kennedy, petitioning him to end the project. The project was finally canceled in 1962, as the AEC faced increased public uneasiness over the environmental risk and potential danger to the Inupiat people.

Concluding Remarks

The developed countries of the world have used the Arctic tundra as a dumping ground, a nuclear playground, and an industrial site. Since the 20th century, Arctic regions have been exploited for mineral and petroleum resources with a mixed level of concern for environment (some in United States and Canada, very little in Russia). The remoteness of the Arctic has made it a target for extensive Russian nuclear testing (Novaya Zemlya), and proposed nuclear engineering (NW Alaska). The warming of the Arctic climate, though not originating from Arctic sources, is melting the sea ice cover, melting the permafrost, and changing tundra ecosystems. Ironically, anthropogenic warming is even now facilitating further human exploitation of the High Arctic for its fossil fuel resources, navigational short-cuts, and previously unobtainable fish stocks. These new incursions into the Arctic may well drive a number of marine mammals and other vertebrate species to extinction, unless strong conservation initiatives are put in place immediately.

Abstract

This article untangles the story of environmental change in the Arctic in the 21st century, and explores some of the interactions between the arctic biosphere, cryosphere, and marine environments. The Arctic region comprises about 30 million km² of land and sea north of the Arctic Circle (66° 33' 44"). The northern polar latitudes comprise an almost equal mix of land and sea. The land regions of the Arctic are divided into the northern sectors of the Eurasian and North American continents, the island of Greenland, and numerous high arctic island groups. The current environmental changes in the Arctic are happening at a pace and an amplitude hitherto unknown. Global warming from anthropogenic GHG emissions is probably having the greatest impacts on Arctic environments. Because of the intricate interactions between land, sea, and ice, the global warming signal is greatly amplified in the Arctic, and all but the most stringent scenarios to reduce GHG emissions will very likely lead to a complete transformation of Arctic environments. No one knows just how the Arctic biota will respond to these environmental changes, but modeling efforts point to a breakdown of existing ecosystems.

Introduction

The Arctic: a remote region that most people will never visit and is often perceived as a frozen, uninhabitable wasteland (Fig. 1). In recent months and years, the Arctic has been in the news on a regular basis. We hear that the sea ice is disappearing, that the

Fig. 1 The High Arctic often appears bleak and forbidding, as in this aerial photo of Ellesmere Island. Courtesy of NASA.

Greenland Ice Sheet is melting, that the Arctic is being subjected to a much higher level of global warming than the rest of the planet. The above statements are a mixture of fact and fiction. As is usual with scientific topics, the facts that are being uncovered are far more complex than were previously thought. This article aims to untangle the story of environmental change in the Arctic in the 21st century, and to explore some of the interactions between the arctic biosphere, cryosphere, and marine environments.

The Physical Environment

As generations of explorers have learned, and the ancestors of the native peoples grasped long ago, the Arctic is a harsh, unforgiving region. The long, dark winters with their bitter cold temperatures, the frozen sea surfaces, the permanently frozen ground, and the great distances between human settlements, make the Arctic a treacherous place. Seemingly small mistakes can be deadly (Fig. 2). The employment of caution in decision making is not just preferable, it is often the only way to survive the circumstances. Yet this physically demanding environment is in many ways incredibly fragile. The plant and animal life of Arctic lands and seas are highly specialized—adapted to survival in some of the harshest environments on Earth. Let us begin with brief descriptions of the physical environments of the Arctic, as a necessary step in setting the stage for later discussion of the ecosystems of the region.

Fig. 2 The logistic errors of 19th century Arctic explorers often ended in death. Park, University of Waterloo, used by permission.

Land vs sea areas

The Arctic region comprises about 30 million km² of land and sea north of the Arctic Circle (66° 33' 44"). The northern polar latitudes are quite different from the southern polar latitudes, where the continent of Antarctica dominates the polar region. The Arctic regions, on the other hand, are almost an equal mix of land and sea. The Arctic Ocean covers 15.6 million km² or 52% of the Arctic. The combined lands of the Arctic cover approximately 14.5 million km², or 48% of the Arctic. The land regions of the Arctic are divided into the northern sectors of the Eurasian and North American continents, the island of Greenland, and numerous high arctic island groups (Fig. 3).

The greatest number of Arctic islands are found in the Canadian Arctic Archipelago, which consists of 36,563 islands above the Arctic Circle in Canada. These islands encompass 1.4 million km² of land. Almost two-thirds of this land is found on the six largest of these islands, including Baffin Island (507,451 km²), Ellesmere Island (196,236 km²), Devon Island (55,247 km²), Axel Heiberg Island (43,178 km²), Melville Island (42,149 km²) and Prince of Wales Island (33,339 km²).

Greenland is the world's largest island, at 2.166 million km². The island spans bioclimatic zones from subarctic in the south to High Arctic in the north (59°–83°N latitude). The Greenland Ice Sheet covers 81% of the land, containing about 2.8 million km³ of ice. The thickness of the ice sheet ranges from about 2–3 km, with most of the ice flowing from the center towards the coasts.

The islands of the Russian Arctic are all situated within the Arctic Circle, scattered through the Barents, Kara, Laptev, East Siberian, Chukchi, and Bering Seas. There are 56 major islands and hundreds of small ones. They cover about 215,500 km² in total.

Svalbard is the northernmost archipelago of Europe, an unincorporated area of Norway. It consists of 61,022 km² of land spread over nine major islands.

Fig. 3 Map of the Arctic, showing the principal vegetation zones (high Arctic, low Arctic, sub-Arctic).

Arctic Ocean circulation

As summarized by Woodgate (2013), the Arctic Ocean is the smallest of the world's oceans. Situated entirely within the Arctic Circle, it contains deep basins, and extensive shelf areas. For centuries, the hallmark of the Arctic Ocean has been its perennial (multiyear) sea-ice. Sea ice forms in the Arctic Ocean and adjacent seas from autumn to early summer. Prior to the 21st century, sea ice-covered half of the Arctic Ocean. Since 2007, minimum sea-ice cover has decreased by around 40%. Average sea ice thickness has thinned by 50%. Prior to the 1980–90s, annual layers of sea ice would build up for several years, thickening the ice pack considerably. However, the extent and thickness of sea ice has been decreasing rapidly in recent years, and multi-year ice has almost disappeared from Arctic waters.

The presence of Arctic sea-ice greatly affects the stratification of the water column, creating a fresher surface layer when it melts, and causing the mixing of surface waters as brine is excluded from ice formation during the freezing process. Arctic Ocean waters are more-or-less uniformly cold ($< 2^{\circ}\text{C}$), so the density of Arctic Ocean waters is primarily determined by salinity.

The Arctic Ocean plays two roles in global ocean circulation. It provides an oceanic pathway between the Pacific and the Atlantic, and it also takes the relatively warm, salty Atlantic surface waters, cools and freshens them, and returns them as deep water to the Atlantic. The continual influx of warm water into the North Atlantic polar ocean keeps the regions around Iceland and southern Greenland mostly free of sea ice year-round. The entrance of Pacific waters into the Arctic is through Bering Strait (Fig. 4). These waters are the dominant source of nutrient inputs into the Arctic Ocean. The entrance of Atlantic currents into the Arctic brings warmer, saltier waters through Fram Strait and the Barents Sea. These routes are both wider and deeper than Bering Strait, and they transport about ten times more water than the inflow from the Pacific. Eurasian rivers contribute roughly two-thirds of the freshwater entering the Arctic. Arctic Ocean waters flow out only into the Atlantic, via the western side of Fram Strait, or through the channels of the Canadian Arctic Archipelago.

Cryosphere

Ice covers many mountain regions, parts of the high Arctic islands, and 80% of Greenland. In addition to the Greenland ice sheet, isolated glaciers and small ice caps cover between 76,000 and 100,000 km² around the periphery of the island. The ice caps on the

Fig. 4 Map of the Arctic region, showing routes of entry and passage of Pacific waters. Drawing after Woodgate, R. (2013). Arctic Ocean circulation: Going around at the top of the world. *Nature Education Knowledge* 4(8), 8.

islands of the Canadian Arctic Archipelago cover more than 100,000 km² of the region. The Svalbard archipelago has eight ice sheets and 180 glaciers. North and east of Svalbard lies Franz Josef Land, a group of 192 islands covering a combined area just over 16,000 km². These Russian islands fall roughly between 80° and 82°N in the Arctic Ocean. Because of their extreme northern location, 85% of the land is glaciated.

Arctic soils

Most arctic soils are in permafrost. This is ground that remains frozen for at least two consecutive years. Permafrost occurs both on land and beneath offshore Arctic continental shelves. Its thickness ranges from < 1 m to > 1000 m. During the summer, the uppermost layer of the ground thaws, forming an “active layer.” Thus, for a few weeks of summer, there is a shallow layer of thawed soil on many Arctic land surfaces. The thickness of the active layer on Arctic landscapes varies from about 0.3 to 4 m. Permafrost regions occupy approximately 22.8 million km² mostly between latitudes of 60°N and 68°N. Permafrost declines sharply in regions north of 67°N, because most of the exposed land surface gives way to the Arctic Ocean.

Because the active layer thaws and re-freezes both on an annual basis and even within the summer season, the instability of the surface and the growth of ice crystals have strong impacts on Arctic vegetation. Nearly all of the Arctic receives so little precipitation that it is properly considered a desert. Yet despite this low precipitation, tundra environments may be rather wet at the surface, and have many thaw lakes. Permafrost blocks the drainage of moisture below the active layer, so almost all of it remains at the surface. Also, very low temperatures keep surface moisture from evaporating back to the atmosphere.

Climates

The most defining feature of Arctic climate is the strong seasonality in sunlight that reaches the surface. It is this strong seasonality in insolation (incoming solar radiation) that drives the large seasonal cycle in surface temperatures in the Arctic. In the winter the surface receives very little or no insolation and the surface loses energy in the form of infrared radiation that is released back out into space.

Meteorological data are scarce in the High Arctic, because of the lack of weather stations. The Canadian Arctic Archipelago has two high latitude stations: Alert and Resolute. The Alert station is on the northern end of Ellesmere Island—the furthest north location in Canada at 82.5°N latitude. The Resolute station is on Cornwallis Island at 74.7°N. The two localities have very similar climates (Fig. 5). Above-freezing temperatures occur only in June to August, and mean daily temperatures do not exceed 5 °C. The average annual temperature is –17.6 °C at Alert and –16.2 °C at Resolute. Precipitation is incredibly low at both sites, as it is throughout much of the Canadian Arctic Archipelago.

The northernmost weather station in Greenland is called Station Nord, situated near the north coast of the island at 81.7°N. The climate profile of Station Nord is quite similar to that of the Alert station, across the Nares Strait on Ellesmere. Average summer temperatures do not exceed 4 °C, the summer season is short, and the average annual temperature is –16.2 °C. The average daily temperature in March is about –28 °C. Station Nord receives 135 mm of precipitation per year—another polar desert region (Fig. 6).

Svalbard, although situated in the High Arctic, receives some warmth from the West Spitsbergen Current (WSC), a branch of the Gulf Stream. The North Atlantic Current flows along the coast of Norway and continues north, where it is called the WSC. Almost 60% of the water entering the Arctic Ocean comes by way of the WSC. By the time the WSC reaches Svalbard, its surface temperature is about 2.75 °C. Even this moderate level of warmth is sufficient to alter the climate of this archipelago. For instance, at the Barentsburg weather station on Spitsbergen (78°N), above-freezing temperatures extend a few weeks into September (Fig. 6). The mean annual temperature is –5.9 °C, and the station receives 424 mm of precipitation per year—more than triple the amount that falls on the northern stations in Canada and Greenland.

Further east, at the Golomyanniy Meteorological Station in the Severnaya Zemlya archipelago of Russia (79.5°N, 90.6°E), the temperature regime is quite similar to those in High Arctic Canada and Greenland: a mean annual temperature of –15 °C, mean July temperature just above freezing, and an average February temperature of –27 °C (Fig. 7). However, this archipelago receives a similar amount of precipitation to Svalbard: 420 mm/year. This moisture comes from storms that drift northeast from the North Atlantic.

Continuing east across the International Dateline, the village of Utqiagvik (formerly Barrow) Alaska lies at the northernmost point of the United States (71.3°N). Because of its relatively lower latitude, this locality has above-freezing average temperatures from June through mid-September. The temperature and precipitation profiles are quite similar to those of the Alert and Resolute stations in Canada (Fig. 7).

Summary of Existing Ecosystems

Birds

The Arctic is seasonally populated by roughly 190 species of birds (Table 1). In contrast to more southerly latitudes, the dominant ecological and taxonomic groups among Arctic birds are waterfowl, shorebirds and seabirds, which constitute 75% of the avifauna. A particularly high species richness is found on both sides of the Bering Strait. Overall, species diversity is more than twice as high in the low Arctic than in the high Arctic. Arctic and subarctic ocean waters are home to huge numbers of sea birds, many of which feed on the abundant shoals of fish that thrive in the cold waters (Fig. 8).

Fig. 5 Climate summary (monthly mean temperature and precipitation) for the Resolute and Alert weather stations in the Canadian High Arctic. Data from Environment Canada.

Fish

At least 127 species of freshwater and diadromous fishes (species that start life in freshwater and then spend most of their lives at sea) occur in Arctic freshwaters. These fish species fall mainly within five families, including more than 50 species of char, whitefishes, and salmon, 25 species of minnows, nine species of sculpins, eight species of perch and six species of lampreys. Freshwater fish diversity decreases with latitude. For instance, there are 40 species living at 60°N, 31 species living at 70°N, three species at 74°N, and only one farther north than this. The greatest freshwater fish diversity is found in areas that were unglaciated during the last ice age, particularly the former landmass known as Beringia. Diversity declines to low levels in regions that were the last to be deglaciated after the last ice age, such as the eastern Canadian Arctic and the coastal fringes of Greenland. Recent evidence suggests that the distributions of freshwater fishes are shifting northwards along river corridors and that diadromous species are becoming established in more northerly marine environments where waters are warming.

Fig. 6 Top: Climate summary (monthly mean temperature and precipitation) for the Station Nord weather station in the northeast Greenland. Data from Danish Meteorological Institute; Bottom: Climate summary (monthly mean temperature and precipitation) for the Barentsburg weather station, Svalbard. Data from the Sveagruva Climate Guide.

According to [Mecklenburg et al. \(2013\)](#), about 633 marine fish species are known from the Arctic Ocean and the adjacent seas, collectively known as the Arctic Gateways ([Table 2](#)). The fish faunas of the Arctic Gateways support some of the largest commercial fisheries in the world. These include 385 fish species in the Bering Sea, 204 species in the Norwegian Sea and 153 species in the Barents Sea. The fish fauna of Arctic Ocean contains less than 90 known species.

Marine mammals

A total of 35 species of marine mammals are found in Arctic waters ([Wilson and Reader, 2005; Table 3](#)). These include two species of sea lions, the walrus, eight species of seals, three species of right whales, five species of rorquals, the gray whale, the beluga and narwhal, the sperm whale, and four species of beaked whale. Three species of dolphins and two species of porpoises swim in Arctic waters. Polar bears are rightly considered marine mammals because they spend much of the year at sea, hunting from pack ice. More than half of the species of the Arctic marine mammal fauna swim in High Arctic waters, though none are restricted to these polar latitudes.

Fig. 7 Climate summary (monthly mean temperature and precipitation) for the Golomyanniy Meteorological Station in the Severnaya Zemlya and for Utqiagvik, Alaska. Top: Weather Data for Golomyanniy Meteorological Station; Bottom: data from US National Weather Service.

Terrestrial mammals

According to Wilson and Reader (2005) there are 63 species of terrestrial mammals on Arctic landscapes (Table 4). These include a surprising diversity of shrews (13 species). There are four species of Arctic hares, three species of pikas, three squirrels, the beaver, and 18 species of voles and lemmings. The large grazers include the Eurasian elk, the moose and the reindeer (caribou), as well as two species of sheep and the muskox. Predators include the gray wolf, coyote, and two species of fox. There are two species of bears and two species of lynx. Rounding out the list of predators are five species of mustelids, ranging from the least weasel, weighing in at 25 g, to the wolverine, weighing an average of 136 kg.

Data from Ganter, B., Gaston, A. J., Anker-Nilssen, T., Blancher, P., Boertman, P., et al. (2013). Birds (Chapter 4). In: Møller, H., Josefson, A. B., Payer, D. (eds.) *Arctic biodiversity assessment, 2013. Status and trends in Arctic biodiversity*. Tromsø, Norway: Arctic Council.

Only about one-quarter of the Arctic terrestrial mammals are found in the High Arctic. Of these only the Wrangel Island collared lemming is restricted to the High Arctic, as it is endemic to this High Arctic island off the northeast coast of Siberia. All the other High Arctic species also inhabit the Low Arctic regions.

Terrestrial vegetation

Because of the harsh climates and brief growing season for terrestrial vegetation, the biological productivity of Arctic landscapes is quite low. The best measure of this is Net Primary Productivity (NPP), the rate of carbon flux from the atmosphere into plants, minus the carbon they use in respiration. In low arctic tundra environments, NPP averages about 600–1000 g/m². In the high arctic polar desert, most regions have less than 50% plant cover, with NPP values of 100 g/m² or less (Gould et al., 2003). For comparison, the average NPP of boreal forest regions is 3500 g/m² and it is 2000 g/m² for temperate grasslands.

As one regional example, let us consider the high- and low-arctic vegetation of Canada, as discussed in Gould et al., 2003. The high arctic vegetation of Canada is dominated by four plant associations, called “Plant functional types.” These include (1) Crustose lichens and mosses; (2) Cushion plants and forbs (an herbaceous flowering plant other than a grass); (3) Dry grasses, mosses and cushion plants; (4) Prostrate dwarf shrubs and cryptogams (ferns, mosses, liverworts, lichens, algae, and fungi). All of these plants grow very close to the ground, thus avoiding the desiccation and tissue damage caused by wind-blown snow crystals. In contrast to the sparsity of vegetation types in the High Arctic, the tundra vegetation of the Canadian Low Arctic comprises seven different plant functional types, ranging from wet grasses and mosses in wetlands to low and tall shrubs (willow, alder, and others) and tussock tundra grasses.

Ecosystem Changes Caused by Climate Forcing

Warming of the Land

Global warming is amplified in the Arctic. Climate data show that air temperatures have risen two to three times faster than elsewhere on Earth since the 1990s (Lindsey, 2017). As shown in Fig. 9, the greatest degree of warming in 2016–17 was centered over the Arctic Ocean, where air surface temperatures were as much as 6 °C warmer than the long-term average (NOAA, 2017).

Table 2 List of families with five or more species of marine fishes from the Arctic Ocean and adjacent seas.

Family	Common name	No. of Arctic species
Rajidae	Skates	28
Clupeidae	Herrings	7
Microstomatidae	Pencilsmelts	8
Platyroctidae	Tubeshoulders	6
Gonostomatidae	Bristlemouths	7
Sternoptychidae	Marine hatchettfishes	5
Stomiidae	Barbeled dragonfishes	5
Paralepididae	Barracudinas	5
Myctophidae	Lanternfishes	16
Macrouridae	Grenadiers	10
Moridae	Deepsea cod	6
Phycidae	Phycid hakes	9
Gadidae	Cods	24
Syngnathidae	Pipefishes and seahorses	5
Scorpaenidae	Scorpionfishes	22
Hexagrammidae	Greenlings	5
Cottidae	Sculpins	69
Hemitriptidae	Sailfin sculpins	6
Agonidae	Poachers	17
Psychrolutidae	Fathead sculpins	11
Cyclopteridae	Lumpfishes	17
Liparidae	Snailfishes	77
Labridae	Wrasses	6
Zoarcidae	Eelpouts	73
Stichaeidae	Pricklebacks	23
Anarhichadidae	Wolffishes	6
Ammodytidae	Sand lances	7
Gobiidae	Gobies	10
Scophthalmidae	Turbots	6
Pleuronectidae	Righteye flounders	31
Total from these families: 527		

Data summarized from Mecklenburg, C. W., Karamushko, O. V., Møller, P. D. R., Lynghammar, A., Christiansen, J. S. (2013). Chapter 6, Fishes. In: Mølltofte, H., Josefson, A. B., Payer, D. (eds.) *Arctic biodiversity assessment, 2013. Status and trends in Arctic biodiversity*. Tromsø: Arctic Council.

The future warming of the Arctic is a certainty. However, the pace and degree of that warming depend to a great extent on the level of greenhouse gas emissions in the coming decades. The Intergovernmental Panel on Climate Change (IPCC, 2013) Fifth Assessment Report (AR5) developed a series of possible future warming scenarios from Coupled Model Intercomparison Project Phase 5 (CMIP5) of the World Climate Research Program. These scenarios are referred to as Representative Concentration Pathways (RCPs). The Fifth Assessment by the IPCC (2013) states that the Arctic will continue to warm more rapidly than the global mean, and that the mean warming over land will be larger than over the ocean and larger than global average warming. In a recent study, Overland et al. (2019) used three sets of RCPs to predict potential future warming trends in the Arctic in the coming decades. Their primary interest was in RCP 4.5, a “middle of the road” scenario in which aggressive but not implausible mitigation leads to temperature rises somewhat above the global mitigation aim of $+2^{\circ}\text{C}$ by the end of the 21st century. This level of warming above the historic long-term average (1900–50) corresponds to GHG concentrations stabilizing near 540 ppm in the second half of the century and globally averaged air temperatures in 2100 of $+2.4 \pm 0.5^{\circ}\text{C}$. A more rigorous mitigation of atmospheric GHG levels, a low emission scenario, is termed RCP 2.6. This ambitious scenario requires both a cessation of anthropogenic GHG emissions over the next few decades and assumes negative emissions in the second half of the 21st century. RCP 2.6 produces a global warming of $\sim 1.6^{\circ}\text{C}$ for 2046–65 and stabilizes more of the Arctic cryosphere than the RCP 4.5 scenario. At the other end of the spectrum of future scenarios is a high end, “business as usual” emission scenario, RCP 8.5. This scenario assumes no measures will be taken to lower GHG emissions.

The best-case scenario (RCP 2.6) prediction for mean annual air temperatures in the Arctic is a warming of $+3.3 \pm 0.9^{\circ}\text{C}$ for the years 2050 and 2100 (Table 5). The RCP 4.5 prediction for mean annual Arctic temperatures is $+4.0 \pm 0.9^{\circ}\text{C}$ for 2050, and $+5.2 \pm 1.5^{\circ}\text{C}$ for 2100. The worst-case scenario (RCP 8.5) for mean annual Arctic temperatures is $+4.8 \pm 1.1^{\circ}\text{C}$ for 2050, and $+9.5 \pm 1.9^{\circ}\text{C}$ for 2100. Both RCP 4.5 and RCP 8.5 temperature predictions would mean extreme transformations of Arctic landscapes and biota by the end of the 21st century. The most severe warming under all three RCPs is predicted to occur during Arctic winters (Table 5). Under RCP 2.6, winter temperatures will warm $+4.7 \pm 1.1^{\circ}\text{C}$ by 2100. Under RCP 4.5, winter temperatures will warm $+7.1 \pm 2.1^{\circ}\text{C}$ by 2100, and under RCP 8.5, winters will warm by a remarkable $+13.3 \pm 2.2^{\circ}\text{C}$ by 2100.

Table 3 Marine mammals of the Arctic region.

Species	Common name	High Arctic	Low Arctic	IUCN status
Bears (Ursidae)				
<i>Ursus maritimus</i>	Polar bear	Yes	Yes	Vulnerable
Sea lions (Otariidae)				
<i>Callorhinus ursinus</i>	Northern fur seal	No	Yes	Vulnerable
<i>Eumetopias jubatus</i>	Steller's sea lion	No	Yes	Endangered
Walrus (Odobenidae)				
<i>Odobenus rosmarus</i>	Walrus	Yes	Yes	Data deficient
Seals (Phocidae)				
<i>Cystophora cristata</i>	Hooded seal	Yes	Yes	Vulnerable
<i>Erignathus barbatus</i>	Bearded seal	Yes	Yes	Least concern
<i>Halichoerus grypus</i>	Gray seal	No	Yes	Least concern
<i>Phoca largha</i>	Spotted seal	Yes	Yes	Data deficient
<i>Phoca vitulina</i>	Harbor seal	No	Yes	Least concern
<i>Phoca groenlandica</i>	Harp seal	Yes	Yes	Least concern
<i>Phoca fasciata</i>	Ribbon seal	Yes	Yes	Data deficient
<i>Pusa hispida</i>	Ringed seal	Yes	Yes	Least concern
Right Whales (Balaenidae)				
<i>Balaena mysticetus</i>	Bowhead whale	Yes	Yes	Least concern
<i>Eubalaena japonica</i>	Pacific Northern right whale			
<i>Eubalaena glacialis</i>	Atlantic Northern right whale	No	Yes	Endangered
Rorquals (Balaenopteridae)

<i>Balaenoptera physalus</i>	Fin whales	Yes	Yes	Endangered
<i>Balaenoptera borealis</i>	Sei whales	No	Yes	Endangered
<i>Balaenoptera acutorostrata</i>	Minke whale	Yes	Yes	Least concern
<i>Megaptera novaeangliae</i>	Humpback whale	Yes	Yes	Least concern
Gray Whale (Eschrichtiidae)				
<i>Eschrichtius robustus</i>	Gray whale	Yes	Yes	Least concern
Dolphins (Delphinidae)				
<i>Orcinus orca</i>	Killer whale	Yes	Yes	Data deficient
<i>Lagenorhynchus albirostris</i>	White-beaked dolphin	Yes	Yes	Least concern
<i>Globicephala melas</i>	Long-finned pilot whale	No	Yes	Data deficient
Beluga and Narwhal (Monodontidae)				
<i>Delphinapterus leucas</i>	Beluga	Yes	Yes	Near threatened
<i>Monodon monoceros</i>	Narwhal	Yes	Yes	Near threatened
Porpoises (Phocoenidae)				
<i>Phocoena phocoena</i>	Harbor porpoise	Yes	Yes	Least concern
<i>Phocoenoides dalli</i>	Dall's porpoise	No	Yes	Least concern
Sperm Whales (Physeteridae)				
<i>Physeter catodon</i>	Sperm whale	No	Yes	Vulnerable
Beaked Whales (Ziphiidae)				
<i>Berardius bairdii</i>	Baird's beaked whale	No	Yes	Data deficient
<i>Mesoplodon stejnegeri</i>	Stejneger's beaked whale	No	Yes	Data deficient
<i>Ziphius cavirostris</i>	Cuvier's beaked whale	No	Yes	Least concern
<i>Hyperoodon ampullatus</i>	Northern bottlenose whale	Yes	Yes	Data deficient
Otters (Mustelidae)				
<i>Enhydra lutris</i>	Sea otter	No	Yes	Endangered

Data from Wilson and Reader (2005).

Aschwanden et al. (2019) used the same three RCP projections to model the response of the Greenland Ice Sheet (GIS) to future warming scenarios. Each of the RCPs yielded different patterns of ice retreat in Greenland. The least severe scenario (RCP 2.6) showed the ice retreating in the west and north, while the moderate scenario (RCP 4.5) showed ice retreat around the island, except for in the highest elevation areas. The most severe scenario (RCP 8.5), in which emissions continue to increase at their present rate, predicted the loss of more than 99% of the ice sheet by 3000. But well before the ice sheet disappears, the progressive melting of the GIS could contribute 5–33 cm to sea level by 2100. Furthermore, Aschwanden et al. (2019) report that in the next 200 years, melting at the present rate could contribute up to 160 cm to global sea level rise. This new estimate is 80 % higher than previous estimates, which forecasted up to 89 cm of sea level rise by 2100 from the melting of the GIS.

	RCP 8.5	+13.3 ± 2.2

Data from Overland, J., Dunlea, E., Box, J. E., Corell, R., Forsius, M., et al. (2019). The urgency of Arctic change. *Polar Science* 21, 6–13. <https://doi.org/10.1016/j.polar.2018.11.008>.

Changes in Arctic climate will entail more than temperature rises. Eythorsson et al. (2019) used global circulation models and remote sensing observations to model future changes in Arctic climate and snow cover. Their results show that across the Arctic warmer climate classes have and will continue to replace polar tundra and cold summer regions, and that by the end of the 21st century the coverage of the most common historic Arctic climate class, cold climate with cold summers and no dry season, will decrease by about 40% (Table 6). The second most common class, Polar tundra, is expected to decrease by 34% during the same period. The authors predict that as these colder climate classes recede further north, climate classes associated with warm and hot summers will expand in coverage by 185% and 733% respectively.

Table 6 Coverage of polar and cold climate classes within the Arctic AMAP boundary and changes between 1951–60 and 2090–99.

		1951–60	2090–99	Net change
	<i>Polar climate</i>	26.4%	17.3%	–35%
	Polar ice	0.4%	0.1%	–86%
	Polar tundra	26.0%	17.2%	–34%
Cold climate	<i>Very cold winters</i>	15.9%	3.1%	–80%
	Dry winters	4.3%	0.1%	–97%
	Dry summers	11.5%	3.0%	–74%
	<i>Cold summers</i>	49.1%	43.8%	–11%
	No dry season	30.4%	18.0%	–41%
	Dry winters	2.9%	1.8%	–41%
	Dry summers	15.8	23.9%	51%
	<i>Warm summers</i>	6.6%	18.7%	185%
	No dry season	4.3%	12.9%	197%
	Dry winters	0.2%	1.2%	518%
	Dry summers	2.1%	4.6%	126%
	<i>Hot summers</i>	2.0%	16.9%	733%
	No dry season	0.9%	7.6%	770%
	Dry winters	0.5%	1.1%	125%
	Dry summers	0.7%	8.3%	1099%

Data from Eythorsson, D., Gardarsson, S. M., Ahmad, S. K., Hossain, F., Nijssen, B. (2019). Arctic climate and snow cover trends—Comparing global circulation models with remote sensing observations. *International Journal of Applied Earth Observations and Geoinformation* 80, 71–81.

Permafrost Degradation

One essential aspect of the Arctic is the interconnectedness of the land, ice and sea. Because of the almost equal balance of land and sea in the northern high latitudes, changing environmental conditions on land also affect conditions in the Arctic Ocean and adjacent seas, and vice versa. Likewise, changes in snow and ice cover affect Arctic soils and vegetation. The rise in atmospheric temperatures over Arctic landscapes has led to an unprecedented rate of melting of permanently frozen soils. These interacting responses to external forcing (i.e., global warming) cause Arctic warming to be amplified in intensity and pace (Fig. 10). Model projections by Overland et al. (2019) show a 20% decrease in Northern Hemisphere permafrost area. Permafrost currently covers an area of

Sparse vegetation of saxifrage, mosses and lichens on Elles Ringes Island, Canada

All photos used with the author's permission.

15 million km². Regardless of the RCP scenario invoked, this area will decrease to 12 million km² by 2040. Under RCP 4.5, there will be a 50% loss of permafrost area by 2080. Under RCP 2.6 and 4.5, the extent of permafrost will stabilize by the end of the century. By the year 2100, permafrost losses will range somewhere between 33% and 85% of their current area, depending on the GHG scenario.

Land Ice Losses

Glacial ice cover will also decline in the coming decades. As summarized in [Table 7](#), [Overland et al. \(2019\)](#) estimate that with a minimum of additional warming of the land and sea, even with a successful limitation of mean global warming near 2 °C, the loss of land ice will not stabilize before the end of the century. Because large bodies of ice have a great deal of thermal inertia, just to be in equilibrium with current temperatures, Arctic glaciers should lose an additional ~35% of their volume.

Changing Plant Communities

Although climate change will affect all the world's ecosystems, those of the Arctic are especially vulnerable because they are limited to the northern fringes of the continents, so they have no way to find refuge as distributions shift northwards. In keeping with the interconnectedness of Arctic environmental changes, changing vegetation patterns will in turn affect regional climates through vegetation-controlled changes in albedo, surface roughness, evapotranspiration rates, energy flux, and snow redeposition ([Gould et al., 2003](#)). With climate warming, ecosystem interactions in the Arctic are generally accelerating due to a large extent to increases in soil processes and associated increased nutrient availability for plant growth ([Klein et al., 2008](#)). Availability of soil moisture has been and will continue to be a major factor limiting plant growth in land areas of the High Arctic. [Klein et al. \(2008\)](#) studied the effects of climate warming on the vegetation of ice-free regions of northeast Greenland. Here, many species of tundra plants rely on insects for pollination. The long-established relationships between specific insect pollinators and their host plants are beginning to break down, as the seasonal timing of plant life cycles changes in response to warming are not necessarily matched by the seasonal cycles of their pollinators. The effects of climate warming that enhance conditions for plant growth in Northeast Greenland and accelerate invasion of new species are necessarily tied to the relationships between specific plant species and their insect pollinators. Accordingly, those plants that are self-pollinated may have an initial advantage in an environment where insects and their plant relationships are being altered by the changing climate.

A recent study by [Bjorkman et al. \(2018\)](#) states that rapid climate warming in the Arctic is driving changes in the structure and composition of tundra ecosystems with potentially global consequences. They point out that as much as 50% of the world's below-ground carbon stocks are held in permafrost soils, and the melting of permafrost in Arctic tundra regions is expected to contribute the majority of warming-induced soil carbon loss over the next century. Plant traits strongly affect carbon cycling and the energy balance of the ecosystem, which can in turn influence regional climates. Strong temperature- and moisture-related spatial gradients in plant species traits related to competitive ability (for example, height) and resource capture and retention (for example, leaf nitrogen and specific leaf area) reflect trade-offs in plant ecological strategy in response to either benign (warm, wet) or extreme (cold, dry) conditions. Their models predict that Arctic warming may lead to a community-level shift towards more acquisitive plant strategies in wet tundra sites, but towards more conservative strategies in drier sites as moisture becomes more limiting.

[Bonney et al. \(2018\)](#) used remote sensing to analyze trends in vegetation changes in north-central Canada from 1984 to 2016. They found that the largest positive and more significant trends in vegetation changes were associated with increased productivity in shrub-dominated environments, especially at, and north of the treeline in localities with favorable growing conditions ([Fig. 10](#)). Smaller and less significant trends in boreal forest environments south of the treeline were likely associated with long-term successional change following disturbance rather than large-scale climatic changes.

Another study of Arctic North American vegetation change in recent years was done on the North Slope of Alaska by [Duchesne et al. \(2018\)](#). Their research concluded that the abundance of tall shrubs had increased in the study region, signaling that these shrubs expanded during the period 2000–2010. They found that of the study locations that exhibited a robust change during that decade, 94% of showed a positive trend toward an increase in shrub cover.

Table 7 Predicted losses of land ice under different greenhouse gas scenarios.

	Scenario	% Ice volume loss
Year 2050	RCP 2.6	–30% ± 11%
	RCP 4.5	–30% ± 10%
	RCP 8.5	–38% ± 10%
Year 2100	RCP 2.6	–33% ± 11%
	RCP 4.5	–50% ± 8%
	RCP 8.5	–85% ± 12%

Changes in Vertebrate Faunas

Warming Arctic climates are facilitating the northward expansion of boreal mammals into the Arctic. One example of this is reported by Rodnikova et al. (2011), who directly observed a red fox (*Vulpes vulpes*) intruding into an arctic fox (*Vulpes lagopus*) breeding den from the southern Arctic tundra of Yamal Peninsula, Russia. The range of the arctic fox has been retracting in the circumpolar tundra zone, while the red fox is expanding its range northwards into the Arctic. The ecologist's observations support the view that direct interference from red foxes on arctic fox breeding dens may be contributing to the range retraction of arctic foxes from the southern limits of the Arctic tundra in Russia. The red fox is not as well-adapted to the extremes of Arctic winters, but as Arctic winter temperatures rise, the red fox has been able to exploit higher latitudes. It is about 1/3 larger and more powerful than the arctic fox, and so out-competes it when the two species come in contact.

Another example of a possible mammalian response to Arctic climate warming concerns the polar and grizzly bears of Canada. Since 2006, eight bears have been found in the Canadian Arctic Archipelago that represent hybrids between grizzly bears (*Ursus arctos*) and polar bears (*Ursus maritimus*). All of these bears were descended from the same female polar bear (Richardson et al., 2017). DNA tests of tissues taken from these bears confirm their hybrid status. Until recently, grizzly bears have rarely been seen been far north of the coast of mainland Canada. In 1991 one or more grizzly bears were documented hunting seals along with polar bears on the sea ice near Melville Island, over 500 km from the mainland coast. Since the start of the 21st century, however, sightings of grizzlies in the Canadian Arctic Archipelago have been on the increase. Grizzly bears have apparently also been extending their range east across northern Canada in the Barren Ground tundra towards Hudson Bay.

Warming of the Seas

Summer sea surface temperatures (SST) in the Arctic Ocean are driven mainly by the amount of incoming solar radiation absorbed by the sea surface. Greater warming occurs in ice-free regions because the open water reflects little light back into space, whereas sea ice reflects a great deal of solar energy. The open ocean reflects only 6% of the incoming solar radiation and absorbs the rest, while sea ice reflects 50%–70% of the incoming energy (Timmermans and Ladd, 2018). This reflectivity is termed “albedo.” Other factors that affect Arctic Ocean SSTs include cloud cover and upper-ocean stratification. In the Barents and Chukchi seas, there is an additional source of ocean heat that comes from the advection of warm water from the North Atlantic and North Pacific oceans, respectively. Arctic SSTs are an essential indicator of the role of the ice-albedo feedback mechanism in any given melt season. As the extent of sea ice cover decreases, more incoming solar radiation is absorbed by the ocean. This forms a positive feedback loop, as the warmer ocean melts more sea ice (Fig. 11). Arctic Ocean ecosystems are greatly influenced by SST. The surface water temperature affects the timing and developmental cycles of plankton.

A report on Arctic SSTs was prepared for NOAA by Timmermans and Ladd (2018). They found that August mean SSTs have warmed significantly, beginning in 1982, for most regions of the Arctic Ocean that are ice-free in August (Fig. 11). However, this warming of SSTs has not been uniform across the Arctic Ocean and adjacent seas. The authors found that spatial patterns of August 2018 SST anomalies relative to the 1982–2010 August mean are due to regional variability in sea-ice retreat, regional air temperatures, and advection of waters from the Pacific and Atlantic oceans. For instance, they note that Northern Barents Sea August mean SSTs show significant cooling trends for 1982–2018 (Fig. 12). This SST cooling trend is attributed to sea ice conditions and ocean heat transport that are unique to this region.

Loss of sea-ice plankton communities

Post et al. (2013) reviewed the biological impacts of sea ice reduction and documented that sea ice loss represents a huge habitat reduction for sea-ice algae and phytoplankton. This habitat loss has severe consequences for the Arctic marine food chain, as these

Fig. 11 Flow chart illustrating the means by which global warming is amplified in the Arctic.

Fig. 12 Diagram illustrating mean annual and long-term trends in sea-surface temperatures in the Northern Barents Sea and the Chukchi Sea. Data from Timmermans, M. L. and Ladd, C. (2018). Arctic report card: Update for 2018. <https://arctic.noaa.gov/Report-Card/Report-Card-2018>.

phytoplankton represent 57% of the primary productivity of the Arctic Ocean. Changes in the timing of sea ice melt disrupt the seasonality of the life cycles of phytoplankton and create mismatches with the timing of zooplankton production. In the past, organic detritus frozen in sea ice was released into the water column as the ice melted in spring. This pulse of organic material was taken up by phytoplankton and zooplankton, facilitating their growth and reproduction as the days grew longer. The burst of biological productivity made its way up the food chain. The phytoplankton fed the zooplankton, which in turn fed crustaceans and small fish. Disruptions of this long-standing pattern are bound to cause breakdowns in the Arctic marine ecosystem.

Loss of sea-ice platform for marine mammals

Sea-ice forms a stable platform from which various marine mammals operate in the winter months. Walrus use the pack ice as a platform for pupping and sea-floor foraging, as do Arctic seals. The Arctic supports a particularly rich diversity of seal species. Probably the most threatened species is the ribbon seal, which lives on the outermost edges of sea ice, near deep water. These are most likely to be affected by loss of habitat as sea ice continues to shrink. Polar bears spend the winter on the pack ice, hunting seals as they come up for air in small openings in the ice. Arctic foxes often follow behind the bears, scavenging seal carcasses after the bears have abandoned them.

Shifting patterns of ocean fish stocks

The presence of sea ice has always limited commercial fishing in the Arctic Ocean. However, as sea-ice declines, commercial fisheries will undoubtedly expand in the Arctic, diminishing fish stocks in the Arctic Ocean. As has been seen in the North Atlantic and other over-fished regions, diminished stocks of predatory fish such as cod alter food-web dynamics. Such changes in food supply will also add extra stress to fish-feeding marine mammals in Arctic waters, such as seals and sea lions.

Impacts of warming seas on marine mammals

There are a number of negative impacts on marine wildlife, due to interacting effects of temperature changes near the shore (Post et al., 2013). In recent years, walrus have been forced to haul out onto the shore for greater periods of time, because activities such as calving that used to take place on sea ice have now shifted to the land. Available hauling-out localities become crowded (Fig. 13), increasing the spread of disease, causing battles between bulls, and contributing to infant mortality. The loss of sea ice also limits the number of days per year that polar bears can hunt seals, and makes their migration between land and sea more difficult. The bears are forced to wait many weeks for the sea ice to form in the autumn, during which time they eat very little. All of these obstacles to hunting reduce their overall fitness. A recent study has shown that the polar bears of the Hudson Bay region of Canada now spend an average of nearly 30 days longer on land than they did 30 years ago. Stirling and Derocher (2012) found that these bears lose nearly 1 kg of body weight each day they're on land, so by the time they return to the sea ice, they will have lost an average of 27 kg, compared with the bears of 30 years ago.

Ecosystem Changes Caused by Regional and Exotic Sources of Pollution

Pollution From Arctic Sources

Since the latter half of the 20th century, Russian companies developed mineral mining, ore smelting and petroleum extraction in their Arctic regions. Since the 1970s, American companies developed the Prudhoe Bay oil field on the Beaufort Sea coast of Alaska.

Local sources (Russian industry in Kola Peninsula and W Siberia)

Mining is the basis of the Kola Peninsula's economy. The Severonikel copper–nickel industrial complex on the Kola Peninsula is one of the largest active sources of SO₂ and heavy metals in northern Europe. A study of soil contamination by heavy metals done by

Fig. 13 Walrus fighting for space on Svalbard. Photo by Daniel Kordan, used with permission.

Kashulina (2017) showed that the current concentrations of Ni and Cu in the upper organic soil horizons in the impact zone reach extreme levels of 9000 and 6000 mg/kg, respectively. The level of copper and cobalt contamination in the soils near the industry exceeds safe background levels by several times. The level of nickel contamination is more than a thousand times the safe background level.

Oil production in Arctic Russia focuses on western Siberia, where 68% of Russian gas and oil extraction take place. The biggest of these fossil fuel production sites are in the Ob River basin, where 300 oil fields have pumped 65 billion barrels of oil since 1965. The Russian government estimates that at least 5% of the oil recovered from western Siberian wells has been spilled onto the tundra since the 1960s. This amounts to 3 billion barrels of oil spilled in the Ob River and adjacent basins. A report by Salmina (2010), a regional ecologist, states that there is no fish life in the Ob, Nadym, Pur, and Sob rivers because of pollution from oil production. The ground water in the oil field regions is so polluted that the petroleum companies must import all drinking water from elsewhere.

Drilling on the Alaskan North Slope has not resulted in any significant oil spills on the tundra. However, a major oil spill did occur near the terminus of the pipeline built to transport the North Slope oil to the southern Alaskan port of Valdez. In March, 1989, a catastrophic oil spill occurred in Prince William Sound, Alaska. The *Exxon Valdez*, an oil tanker bound for Long Beach, California, struck a reef close to shore in Prince William Sound and spilled 37,000 metric tons of crude oil over the next few days. The oil eventually contaminated 2100 km Alaskan of coastline, of which 320 km were heavily or moderately affected. Despite the extensive cleanup attempts, less than 10% of the oil was ever recovered. The immediate effects of the spill included the deaths of as many as 250,000 seabirds, at least 2800 sea otters, approximately 12 river otters, 300 harbor seals, 247 bald eagles, and 22 orcas, and an unknown number of salmon and herring.

Long-distance transport of aerial pollutants

For the past half-century, air pollution from exotic sources has been acidifying arctic lakes, even though the source of pollution is thousands of km to the south. Such changes are probably linked to multiple factors, including air pollution, warming temperatures, and increased levels of ultra-violet radiation. Within the Arctic there has been minimal direct production and use of industrial contaminants like persistent organic pollutants (POPs) and mercury (Hg). However, POPs are carried into the Arctic from more southerly latitudes via long-range atmospheric transport as well as via ocean currents and rivers.

Effects of global warming on Arctic pollutants

A warming Arctic will likely release previously sequestered mercury from permafrost, glaciers, ice and snowpack. Warmer temperatures will also alter what happens to this newly-released mercury, such as its transfer between air, ocean and terrestrial compartments, as well as altering mercury atmospheric chemistry and geochemistry (Foster et al., 2019). Increased shipping through the Northwest Passage will introduce local sources of anthropogenic mercury. Foster et al. (2019) did a meta-analysis of 83 time series datasets, and found no consistent temporal trend in mercury pollution levels over the past 30 years. However, they did find

a longitudinal gradient in the data, with mercury decreasing from west to east (i.e., Canadian/Greenland to North Atlantic/European Arctic). Mercury is a potent neurotoxin that causes physiological, neurological, behavioral, and reproductive harm to wildlife, including seabirds. Mercury readily biomagnifies, resulting in increasing concentrations as it moves up the food chain. Because these birds are relatively high up on the food chain, they are subject to higher levels of contamination.

While the levels of POPs have been declining in the Arctic in recent years, global warming may at least temporarily reverse that trend. This is because increasing temperatures provide the necessary thermodynamic forcing to drive POPs out of reservoirs, such as soil, vegetation, water and ice, and into the atmosphere where they can be transported by winds, eventually reaching locations where lower temperatures prevail, such as the Polar Regions (Ma et al., 2016). The major environmental concern with POPs is their toxicity. At high enough levels of exposure, POPs have been shown to cause endocrine disruption, reproductive and immune dysfunction, neurobehavioral and developmental disorders, and cancer.

Effects of air pollution on terrestrial ecosystems

Dietz et al. (2019) reviewed the toxic effects of environmental contaminants that accumulate in fatty tissues of Arctic animals. These lipophilic contaminants, such as POPs and methylmercury (MeHg) bioaccumulate in Arctic organisms and biomagnify through Arctic food webs, generating concern for the health of exposed wildlife and for indigenous populations that consume the meat of these animals as part of their traditional diet. The harmful effects of many POPs, largely comprised of chlorinated, brominated and/or fluorinated organo-halogenated compounds (OHCs), on human and environmental health have long been recognized.

Chemicals and heavy metals are not the only aerial pollutants affecting Arctic flora and fauna. Burger and Lichtscheidl (2019) examined the impacts of radioactive strontium contamination in Arctic ecosystems. Much of the strontium emissions in the Arctic stem from nuclear reactor waste and from above-ground nuclear testing done in the latter half of the 20th century. Strontium particles are dispersed throughout the global atmosphere, along with other radionuclide species. Analysis of radionuclides that are deposited on Arctic tundra vegetation has shown that 65% of these radioactive particles, including Sr-90, accumulate in the top three cm of vegetation cover (especially noted on tundra lichen cover). It also accumulates in the uppermost layers of soils, from whence it migrates into plant tissues. Once deposited, Sr-90 is consumed by herbivores, including caribou and muskox. From there it passes up the food chain to human hunters of these animals. Exposure to Sr-90 increases the risk for several diseases including bone cancer, cancer of the soft tissue near the bone, and leukemia.

Pollution in the Arctic Ocean and Adjacent Seas

Pollution of Arctic Ocean waters used to be caused almost exclusively by long-distance transport of pollutants via ocean currents or from rivers draining into the Arctic Basin. As Arctic sea ice is becoming less of a threat to shipping and offshore petroleum drilling, local pollution is in the process of becoming a serious problem in Arctic waters.

Local sources

Increased human access to the Arctic Ocean will enable the development of new oil and gas fields on the continental shelves surrounding the Arctic Ocean. Drilling of new offshore oil and gas wells is already being planned in these waters, as sea ice retreats. Such activities will alter habitats, pollute the water, and disturb marine life. Of particular note is the disturbance of the region's rich marine mammal fauna. Offshore oil and gas facilities will disturb marine mammals through noise from seismic surveys, shipping, and drilling. Vergeynst et al. (2018) have reviewed the process of biodegradation of spilled oil in Arctic waters near Greenland. They point out that the new economic developments such as shipping and oil exploitation bring with them increased risks of marine oil spills. In warmer ocean waters, microorganisms play a key role in degrading and reducing the impact of oil spills. However, in the Arctic, and in particular in pristine waters, the self-cleaning capacity and biodegradation potential of the natural microbial communities remain unknown. Some of the characteristic features of Arctic waters are low temperature, the seasonal presence of sea ice, oligotrophic (nutrient-limited) environments, poor microbial adaptation to hydrocarbon degradation, mixing of stratified water masses, and massive phytoplankton blooms and suspended sediment plumes. All of these characteristics of Arctic seawater tend to work against the biodegradation of spilled oil, whether the source of the spills is oil drilling or fuel oil accidentally released from large ships passing through the Arctic.

Chronic noise pollution is increasing in Arctic waters, producing cumulative impacts that extend beyond the continental shelf regions where these activities will take place. Already, bowhead whales have been observed to shift migratory routes in the Beaufort Sea to avoid noise from oil and gas development activities, such as drilling. If preferred habitats for breeding, calving, feeding and migration are disturbed over large areas, the overall fitness of marine mammal populations in the Arctic Ocean will decline.

Ocean transport ships are a major source of noise pollution in the ocean. The emerging tanker traffic predicted to take place in the Arctic Ocean in the coming decades will increase the impacts on marine mammals from noise pollution, but also from other disturbances, such as the release of pollutants into the water. If large ships have to rely on ice-breakers to open shipping lanes, then the ice-breaking ships also add to these disturbances, as they are known to disrupt birthing of seal pups on the ice.

Fig. 14 Map of the Northern Hemisphere showing multiple sources of pollution entering the Arctic. After Burkow, I. C. and Kallenborn, R. (2000). Sources and transport of persistent pollutants to the Arctic. *Toxicology Letters* **112–113**, 87–92.

Long-distance transport of chemical pollutants

Burkow and Kallenborn (2000) have mapped multiple sources of pollution entering the Arctic. These pollutants arrive in the North via air currents, ocean currents, on drifting sea ice, and from rivers emptying into the Arctic basin (Fig. 14). Some toxic chemicals and heavy metals are produced either in or near to the Arctic, in Scandinavia and northern Russia. Other pollutants travel thousands of kilometers before arriving in the Arctic.

Effects of ocean pollution on Arctic ecosystems

Just as on land, POPs and methylmercury (MeHg) bioaccumulate in Arctic marine organisms and biomagnify through marine food webs. Unfortunately, POPs such as dioxins and polychlorinated biphenyl (PCB) and heavy metals such as mercury tend to accumulate in the tissues of many marine organisms, from zooplankton to fish and marine mammals. These pollutants tend to accumulate in the fatty tissues of marine mammals, so their concentrations become far higher than those found in organisms lower down the food chain. Tracing the pathways of this biomagnification up the marine food chain, Braune et al. (2005) showed that the concentrations of PCBs in zooplankton range from about 15 to 55 ng/gram of dry weight (Fig. 15, top). Beluga whales eat fish that have eaten other fish and zooplankton. The concentrations of PCBs in beluga blubber in the Canadian arctic range from about 3000 to 5000 ng/gram of blubber, a concentration about 150 times that found in zooplankton (Fig. 15, middle). Polar bears eat mainly ringed seals in these waters. The seals eat fish that have eaten other fish and zooplankton. The concentration of PCBs in polar bear fat is about 1000–2500 ng/gram of fat (Fig. 15, bottom). Dietz et al. (2019) identified quantifiable effects of POPs and mercury on the health of various Arctic marine mammals. They found that these pollutants interfere with many aspects of vertebrate physiology. In marine mammals (the best studied group), the pollutants disrupted or damaged vitamin metabolism, immune function, thyroid and steroid hormone balances, oxidative stress, tissue pathology, and reproduction capacity.

Conclusions

Environmental change in the Arctic in the 21st century is happening at a pace and an amplitude hitherto unknown in this region. Scientists are trying to keep track of the changes, and their effects on Arctic biota. Global warming from anthropogenic GHG emissions is probably having the greatest impacts on Arctic environments. Because of the intricate interactions between land, sea and ice, the global warming signal is greatly amplified in the Arctic, and all but the most stringent scenarios to reduce GHG emissions will

very likely lead to a complete transformation of Arctic environments. It is already clear to see that the sea ice of the Arctic Ocean and adjacent seas will be gone in a few decades at most. The 2019 sea ice minimum (Fig. 16) was the second lowest on record. No one knows just how the Arctic biota will respond to these environmental changes, but modeling efforts point to a breakdown of existing ecosystems.

Abstract

Plant-herbivore interactions are a key driver of ecosystem dynamics in arctic regions. Herbivores can influence plants, plant communities and ecosystem processes, but to which extent they do so and in which direction depends on a complex set of environmental factors. Plant-herbivore interactions in arctic environments occur under particular environmental conditions, characterized by marked seasonality, short growing seasons, low temperatures and low primary productivity. These conditions limit the ability of tundra plants to respond to herbivory and imply that herbivores require specific adaptations to cope with the highly heterogeneous plant production. Here, we provide an overview of arctic herbivores and their influences on plants, vegetation, and ecosystem processes in arctic environments, and how these interactions are likely to be altered by the rapid environmental changes happening in this region. We review current efforts and methods used to study plant-herbivore interactions in the Arctic, including recent developments related to invertebrate herbivory and managed grazing systems. Herbivory is an active topic of research in arctic environments given the potential of herbivores to counteract some of the changes associated with recent environmental changes. The field is moving forward, and the increased coordination of research efforts will allow generating more robust predictions of the consequences of the rapid ongoing environmental changes in this region.

Introduction

General ecological theory predicts that the strength of biotic interactions, including herbivory, will be weaker at higher latitudes. According to the latitudinal herbivory hypothesis (LHH), the intensity of herbivory decreases toward the poles (Coley and Barone, 1996; Pennings et al., 2009), so herbivory in arctic ecosystems is expected to be low compared to ecosystems farther south. While this might be generally true (Kozlov et al., 2015) and plant biomass consumption might be relatively low in tundra (Mosbacher et al., 2016; Barrio et al., 2017), many studies have acknowledged the importance of herbivory in these high-latitude systems (Mulder, 1999; Olofsson et al., 2012; Oksanen and Oksanen, 2000).

Herbivory is the interaction between plants and the animals that eat them. It is, in essence, a local process where an animal interacts with a plant. However, the impacts of herbivory go beyond the direct effects of consumption and can have consequences at larger spatial and temporal scales (Yu et al., 2017; Olofsson et al., 2012). Herbivores can affect plants through nonconsumptive activities that change the physical environment, like trampling, or that alter nutrient availability, for example through waste deposition (Barthelemy et al., 2018). Further, through their influence on vegetation structure and composition, herbivores can alter ecosystem processes and initiate feedbacks to the climate system (Te Beest et al., 2016). However, the impacts of herbivory are highly variable and depend on where and when the interaction takes place. The causes of this variation are not well resolved but presumably the role of herbivory is modified by ecosystem-specific conditions, including human management (Normand et al., 2017; Biuw et al., 2014), the coevolutionary history between plants and herbivores (Bryant et al., 2014), grazing history (Väisänen et al., 2014), nutrient availability (Gough et al., 2012) or variations in geological substrate (Bråthen et al., 2007). Understanding what drives this variability is critical to forecast the responses of tundra ecosystems to ongoing environmental changes.

One of the particularities of herbivory in arctic ecosystems is the environmental conditions under which this interaction takes place. Arctic ecosystems are markedly seasonal, with short growing seasons, low temperatures and low plant productivity (Jefferies

et al., 1994). Nutrient and water availability limit plant growth and the ability of tundra plants to respond to herbivory (Chapin, 1980). In turn, herbivores need specific adaptations to cope with the limited plant production and the strong seasonality. We provide an overview of arctic herbivores and their influences on plants, vegetation, and ecosystem processes in arctic environments, and how these interactions are likely to change under rapid environmental changes in this region. Most research has focused on vertebrate herbivory (mammals and birds), and these results have shaped our current understanding. The effects of invertebrate herbivory are still poorly known, and for this reason are discussed in a separate section. Finally, we review current efforts and methods used to study herbivory in the Arctic and suggest further directions for research. Overall, our intention is to expand upon two core references in arctic herbivory which focused mainly on tundra ecosystems of North America (Mulder, 1999; Jefferies et al., 1994). Specifically, we include some recent developments related to invertebrate herbivory and managed grazing systems in ecosystems around the circumpolar Arctic.

Arctic Herbivores

Herbivores in the Arctic encompass a variety of organisms, from large and small mammals and birds to invertebrates (Barrio et al., 2016a; Fig. 1). There are 73 species of vertebrate herbivores in the Arctic, with the greatest species richness associated with areas of higher primary productivity (Barrio et al., 2016a). We know less about the diversity of invertebrate herbivores, but in general, the proportion of herbivorous taxa declines toward higher latitudes (Danks, 1986). The composition of herbivore communities is an important factor determining the impacts of herbivores on vegetation, because different herbivores can have complementary effects on vegetation (Metcalfe and Olofsson, 2015; Ravolainen et al., 2014). For example, in the forest-tundra ecotone, intense summer browsing by reindeer in birch forests affected by severe moth outbreaks can slow down forest recovery by preventing the establishment of new trees (Biuw et al., 2014). Similarly, small mammals (voles and lemmings) can contribute to maintaining the distinct vegetation of historical reindeer milking grounds even decades after their use has been discontinued (Egelkraut et al., 2018a).

Herbivores in the Arctic have evolved different strategies to cope with the harsh environmental conditions and the low primary productivity, and the strategy they adopt will have important consequences to their interactions with plants (Schmidt et al., 2018). The seasonal availability of resources and the timing of life events is critical to the survival of arctic herbivores. To avoid winters, some vertebrate herbivores migrate within or outside the Arctic, others hibernate, and some others, like voles and lemmings, remain active in winter in the subnivean space (Soininen et al., 2015). Invertebrate herbivores have a number of adaptations to arctic environments, including slow growth and cold-resistant overwintering stages (Bale et al., 2002).

Productivity of arctic ecosystems is low, typically characterized by aboveground growth of less than 300 g DWT m⁻² y⁻¹ but varies greatly among habitats (Shaver and Chapin, 1991) or at even smaller spatial scales (Henry, 1998). Differences in soil moisture and snow accumulation driven by topography can create a highly heterogeneous landscape and influence plant-herbivore

Fig. 1 Arctic herbivores encompass a variety of organisms, from large (A; Svalbard reindeer *Rangifer tarandus platyrhynchus*), small mammals (B; Norwegian lemming *Lemmus lemmus*) and birds (C; rock ptarmigan *Lagopus muta*), to invertebrates (D; caterpillar of the moth *Gynaephora groenlandica*). Differences in their feeding strategies have important consequences to their interactions with plants. Photo credits: Eeva Soininen (A–C), Isabel C Barrio (D).

interactions (Kankaanpää et al., 2018). For example, the timing and distribution of snow mediate the impact of ptarmigan browsing on shrubs, with heavier browsing on branches that protrude the snowpack (Tape et al., 2010). Local topography can also influence patterns of foliar concentrations of nitrogen and phenolic compounds through its effects on snow accumulation and plant phenology, which ultimately affects the intensity of herbivory (Torp et al., 2010).

Arctic herbivores tend to be generalist in their food selection, in the sense that they can eat plants from a range of taxonomic groups (Jefferies et al., 1994), but they feed selectively and show preferences for certain species or plant groups, and between plant parts within an individual (Schmidt et al., 2018). Many invertebrate herbivores show narrower host selection at higher latitudes, probably due to a tighter phenological bond between the herbivore and its host (Hodkinson, 1997). Both forage quantity and quality are important determinants of habitat and food selection of vertebrate arctic herbivores (Iversen et al., 2014; van Der Wal et al., 2000). Selectivity in food preferences can change along the growing season following phenological changes in food quality. Herbivores tend to be more selective in their food and habitat choices early in the season when more palatable phenological stages are available (Iversen et al., 2014).

Populations of some arctic herbivores fluctuate over time, which results in temporal variation of grazing impacts on vegetation. For instance, the population cycles of voles and lemmings drive synchronous fluctuations in plant biomass (Olofsson et al., 2012), and periodic outbreaks of geometrid moths can cause vegetation shifts in the tundra-forest ecotone (Jepsen et al., 2008). Population cycles of vertebrate herbivores have been extensively studied in boreal and arctic ecosystems because of their influence on ecosystem functioning (Ims et al., 2008; Ims and Fuglei, 2005). The expected dampening of population cycles under climate warming will likely have important consequences to the functioning of arctic ecosystems (Box 1).

Responses of Tundra Plants to Herbivory

Herbivores influence plant performance by removing plant biomass, altering resource availability and changing the physical environment (Mulder, 1999). It has been hypothesized that herbivore effects in arctic environments, where abiotic factors are the main drivers of plant community structure, occur through the influence of herbivores on abiotic factors (Mulder, 1999), as changed abiotic conditions can affect the competitive ability of different plant species (van der Wal and Brooker, 2004). The influence of herbivores on plants depends on many factors, including resource availability, levels of competition and timing of biomass removal. For example, deciduous shrubs invest in leaf production earlier in the season so they are more sensitive to spring herbivory (Chapin, 1980). Moderate grazing by geese early in the season increased net aboveground primary production of the grass *Puccinellia phryganodes*, but the ability of swards to recover from the effects of grazing decreased over the course of the summer (Hik and Jefferies, 1990). However, throughout the season, the deposition of goose droppings on grazed swards (and associated nutrient recycling) contributed to the rapid regrowth of grazed plants (see below).

Responses to Biomass Removal

Tundra plants can be divided into functional groups depending on the traits that control their response to environmental change and herbivory (Chapin et al., 1996). These functional groups correspond broadly with growth forms, and are defined by their growth rates and woodiness (Chapin et al., 1996). Graminoids, and to a lesser extent deciduous shrubs, recover more easily from herbivory because they usually have large belowground reserves, and higher rates of photosynthesis, leaf turnover and nutrient absorption (Chapin, 1980). Tundra sedges and rushes, like most graminoids, are well adapted to herbivory and respond to defoliation by rapid regrowth of leaves (Henry, 1998; Bråthen and Odsasz-Albrigtson, 2000; Jónsdóttir, 1991). Woody species are generally less able to respond positively to herbivory than graminoids, but some deciduous shrubs like willows can compensate moderate levels of browsing by producing longer shoots and more buds (Christie et al., 2014). Evergreen shrubs are generally less preferred by vertebrate herbivores (Christie et al., 2015) but can be vulnerable to trampling and browsing where animals are at high densities.

Herbivores can influence plant population dynamics by altering flower or seed production (Cooper and Wookey, 2003; Kuijper et al., 2006), by consuming seedlings (Egelkraut et al., 2018a; Ravolainen et al., 2014) or by altering the availability of microsites for seed germination. For example, browsing by ptarmigan and moose on distal axillary buds that would become catkins interferes with

Box 1 Dampening of small rodent cycles

Climate forcing seems to be the general underlying cause of the collapse of population cycles of many species over the last decades (Ims et al., 2008). Winter weather and snow conditions affect the dynamics of small rodents through changes in the quality and availability of subnivean space (Kausrud et al., 2008) that provides small rodents with shelter from predators, thermal insulation, and access to food. Some species of rodents, like lemmings, are more sensitive than others to climate variation (Ims et al., 2011), but cycles are determined by complex interactions. The collapse of population cycles will have severe consequences to the functioning of arctic ecosystems through the disruption of pulses in the flow of resources (Ims et al., 2008). Dampening of the population cycles of small rodents are reflected in dramatic declines in northern predators (Schmidt et al., 2012; Gilg et al., 2009) and changes in vegetation (Rydgren et al., 2007; Olofsson et al., 2012). The magnitude of these trophic cascades however, is context specific and will depend for example on the food web structure at a given site (Schmidt et al., 2012).

sexual reproduction of felleaf willow (*Salix alaxensis*) (Christie et al., 2014), and continuous grazing by reindeer (Cooper, 2006; González et al., 2010) and geese (Kuijper et al., 2006) can deplete seed and propagule banks in many tundra sites.

Responses to Altered Nutrient Availability

Given the limited availability of nutrients in arctic ecosystems, plant-herbivore interactions in northern latitudes are driven by nutritional pulses (Jefferies et al., 1994). Under some circumstances, plants can respond to defoliation with rapid regrowth (Jefferies et al., 1994), resulting in an increase in quality, quantity or accessibility of food, which in turn influence the population dynamics of both plants and herbivores (Person et al., 2003). These areas are called grazing lawns (McNaughton, 1984; Fig. 2), or their equivalent in browsing systems, browsing hedges (Christie et al., 2014). The mechanisms that allow these responses include fertilization via feces and urine (van der Wal et al., 2004; Hik and Jefferies, 1990), and changes to plant physiology and development that facilitate compensatory growth (McNaughton, 1983). These high-quality foraging areas are maintained by repeated grazing and have a greater carrying capacity than nongrazed areas (Jefferies et al., 1994; van der Wal, 2006). Some examples of the creation of these grazing lawns in northern ecosystems are *Carex* swards grazed heavily by Black Brant geese (*Branta bernicla*) in Alaska (Person et al., 2003), tundra vegetation grazed by brown lemmings (*Lemmus trimucronatus*) in northern Alaska (Johnson et al., 2011), graminoid-dominated mires used by muskoxen (*Ovibos moschatus*) in Greenland (Falk et al., 2015) and graminoid dominated vegetation grazed by high densities of reindeer in Fennoscandia (Olofsson et al., 2004) (Fig. 2).

Herbivores can thus cause profound changes in the structure and functioning of plant communities (Johnson et al., 2011). For example, reindeer can drive vegetation shifts from moss- or shrub-dominated tundra to graminoid-dominated vegetation (van der Wal, 2006). These shifts in vegetation are dramatic and relatively sudden, and have been linked to the large-scale transition from grass-dominated steppe to moss dominated tundra in Beringian ecosystems at the end of the Pleistocene following the extinction of megaherbivores (Zimov et al., 1995). A contemporary example of these vegetation shifts are the historical reindeer milking grounds, where semi-domesticated reindeer were gathered. These swards can persist long after discontinuation of their use, effectively functioning as alternative stable states (Egelkraut et al., 2018a) and can be maintained by plant-soil feedbacks (Egelkraut et al., 2018b). In these systems, plant-herbivore interactions are strongly dependent on high rates of nutrient turnover via positive feedback processes, that can result in intense foraging by the herbivores (Jefferies et al., 1994).

Fig. 2 Arctic herbivores induce changes in vegetation. Under some circumstances, fertilization through feces and urine together with repeated grazing that stimulates plant re-growth can maintain high-quality foraging areas. These grazing lawns are dominated by grazing-tolerant species with high nutrient concentrations and can support a higher density of herbivores than nongrazed vegetation. Four examples are illustrated, but grazing lawns are very common across the arctic region. Responses to Altered Physical Environment

As well, herbivores can cause changes in community and ecosystem functioning as a result of altering physical conditions. Trampling by reindeer and geese compacts the moss layer, resulting in increased summer soil temperatures that, together with grazing and fecal deposition promote the productivity and expansion of graminoids (van der Wal et al., 2004). Trampling can also affect the competitive abilities of plants, favoring plants that are less sensitive to trampling (Jónsdóttir, 1991). Other physical disturbances, such as belowground feeding by geese (grubbing) affect plant communities differently depending on their intensity and extent; the recovery after disturbance depends on initial biotic and abiotic properties of the community (Speed et al., 2010a,b). Indeed, some heavily grazed communities may undergo a complete change in their equilibrium state and never recover (Jefferies et al., 2006).

Effects of Herbivory on Ecosystem Processes in the Arctic

The effects of herbivory in arctic ecosystems extend beyond changes in the structure and composition of vegetation. For example, herbivores can alter nitrogen and carbon cycling and net ecosystem productivity. Further, through changes in the structure of vegetation, herbivores can influence the energy balance of tundra ecosystems, with consequences to global climate feedbacks (Cohen et al., 2013; Te Beest et al., 2016).

Effects of Herbivores on Nutrient Cycling

Herbivores can influence nutrient cycling of arctic ecosystems directly through waste and urine deposition (Barthelemy et al., 2018; Hik and Jefferies, 1990; van der Wal et al., 2004), or indirectly through changes in plant litter quality and degradability (Olofsson and Oksanen, 2002), or through changes in soil microbial activity. For example, increased soil temperatures in trampled areas can enhance microbial decomposition processes (Olofsson et al., 2004). Herbivores can either accelerate or decelerate nutrient cycling. It is generally assumed that herbivores increase N availability and enhance primary production in nutrient-rich environments, while they have negative effects on nutrient cycling in nutrient-poor environments. However, these patterns do not always hold (Sitters et al., 2017; Stark et al., 2015a,b) and might be masked through the transport of nutrients across the landscape by herbivores from more to less fertile sites (Stark et al., 2015a,b). For example, muskoxen in Greenland forage mainly in graminoid dominated areas and use snowbed habitats for resting, which results in a net nutrient transfer from nitrogen-rich to nitrogen-poor habitats (Mosbacher et al., 2016).

Herbivores can also influence carbon (C) balance in arctic ecosystems (Falk et al., 2015; Sjögersten et al., 2008). Atmospheric CO₂ is fixed by plants through photosynthesis, so consumption of photosynthetic tissue by herbivores can suppress C uptake. As well, other changes brought about by herbivores, like altered plant C allocation, soil processes and changes in the structure and composition of plant communities, can influence C balance in tundra ecosystems (Cahoon et al., 2012; Väisänen et al., 2014; Metcalfe and Olofsson, 2015; Falk et al., 2015; Yläne et al., 2015). For example, early season belowground foraging by pink-footed geese strongly influenced net ecosystem exchange, reducing C sink strength (van der Wal et al., 2007). Similarly, long-term heavy grazing by reindeer in northern Norway caused vegetation shifts toward communities dominated by graminoids, which are a weaker C sink than lightly-grazed communities dominated by dwarf shrubs (Väisänen et al., 2014). In this sense, the net C sequestration associated with the shrubification of the Arctic predicted under warming scenarios could be counteracted by herbivores (Cahoon et al., 2012).

Effects of Herbivores on Climate Feedbacks and Energy Budgets of Tundra

Large herbivores can influence the energy balance of tundra ecosystems (Te Beest et al., 2016; Cohen et al., 2013). By reducing plant height and vegetation cover, grazing can create surfaces that reflect more solar radiation into the atmosphere, that is, with higher albedo, during the growing season (Shao et al., 2017; Te Beest et al., 2016). For example, high reindeer densities in some parts of Fennoscandia have reduced shrub height and abundance (Olofsson et al., 2004). These structural shifts in vegetation increase summer albedo, resulting in lower energy absorption and an overall cooling effect (Te Beest et al., 2016), which has feedback implications onto the local climate (Shao et al., 2017).

In addition, changes in vegetation structure brought about by herbivores can also affect albedo during snowmelt (Cohen et al., 2013; Biuw et al., 2014), a period that is critical to the energy budget of tundra ecosystems. Snow is a highly reflective surface that helps keep air temperatures low by reducing the absorption of solar radiation. Taller vegetation protrudes above the snowpack, reducing its albedo and accelerating snowmelt (Cohen et al., 2013). Tall and more abundant vegetation in seasonal pastures may result in earlier snow melt and increased ground heating during the snowmelt season, relative to pastures grazed year-round (Cohen et al., 2013).

Invertebrate Herbivory in Tundra

The role of invertebrate herbivores in tundra ecosystems has received less attention than that of vertebrate herbivores, in part because their impacts are less noticeable and invertebrate herbivores are not harvested by arctic residents. The proportion of

herbivore taxa among invertebrates declines toward higher latitudes (Danks, 1986), and invertebrate herbivores are generally less abundant in tundra (Haukioja, 1981). Therefore, it has been generally assumed that the effects of invertebrate herbivores in high-latitude ecosystems are negligible (Haukioja, 1981; MacLean, 1981). However, outbreaks of invertebrate herbivores can cause dramatic losses of plant biomass in the forest-tundra ecotone (Jepsen et al., 2008; Kaukonen et al., 2013; Bjerke et al., 2014) and in some tundra ecosystems (Post and Pedersen, 2008; Lund et al., 2017). Massive defoliation during outbreaks can have large impacts on nutrient cycling of subarctic birch forests (Kaukonen et al., 2013; Parker et al., 2017) and can cause shifts from forests to open vegetation (Jepsen et al., 2013; Olofsson et al., 2013).

In contrast, background herbivory is the chronic consumption of plant biomass when invertebrates occur at low densities (Kozlov and Zvereva, 2017), and it is ubiquitous in tundra (Barrio et al., 2017). Recent estimates of the amount of plant biomass removed by invertebrate herbivores at background levels in tundra are around 1% (Kozlov et al., 2015; Barrio et al., 2017). Similarly, the contribution of invertebrate herbivores to N and C cycling in tundra is small relative to that of invertebrates involved in detritus-based food webs (Koltz et al., 2018). However, background invertebrate herbivory may still play an important ecological role. Studies from boreal forests suggest that background invertebrate herbivory can have strong effects on plant growth (Zvereva et al., 2012) and seed germination (Lundbye et al., 2012), and can influence nutrient cycling at the ecosystem level (Metcalfe et al., 2016). Background herbivory in tundra can also affect community processes, by affecting foraging choices of other herbivores (Barrio et al., 2013).

Changes associated with climate warming in arctic ecosystems will also influence invertebrate herbivores and their effects on tundra plants. The intensity of herbivory is expected to increase with warmer temperatures (Barrio et al., 2017), and this increase is predicted to be stronger at higher latitudes (Kozlov, 2008; Wolf et al., 2008). Warmer temperatures increase the intensity of invertebrate herbivory (Barrio et al., 2016; Birkemoe et al., 2016), as well as the prevalence and intensity of insect outbreaks in high latitude ecosystems (Jepsen et al., 2013). What such increases in the intensity of background invertebrate herbivory will mean for tundra plants remains to be investigated. The strong recovery of tundra plant communities following insect outbreaks in West Greenland suggests that tundra ecosystems may be well adapted and resilient to insect outbreaks (Dahl et al., 2017; Post and Pedersen, 2008). However, environmental changes can reduce the ability of plant communities to recover after outbreaks (Dahl et al., 2017).

Trends and the Future

Arctic ecosystems are changing rapidly as a result of changes in climate and in human management, and the outcomes of plant-herbivore interactions will be modulated by (or can mediate the responses to) these major external drivers of tundra ecosystems. The influence of these drivers will depend both on how their effects on plants determine resource availability and quality for herbivores, and on how their effects on herbivores affect net primary production and community composition. For example, increased primary production in response to warmer temperatures can support larger herbivore populations, which in turn can intensify herbivore pressure leading to habitat degradation and subsequent reduction of the carrying capacity (Madsen et al., 2011).

Climate Change

Arctic regions have experienced the fastest rates of warming over the past 30 years (IPCC, 2013). Arctic ecosystems are sensitive to variability in temperature (Seddon et al., 2016), and warming has been identified as one of the major causes of biodiversity loss in the Arctic (Post et al., 2009).

Changes in plant community composition and structure have been documented throughout the Arctic as a response to warming (Elmendorf et al., 2012), for example through a rapid expansion of woody shrubs (Myers-Smith et al., 2015). Interestingly, it seems that the same traits that allow fast responses of plants to warming also make them more susceptible to herbivory (Olofsson and Post, 2018). Vertebrate herbivores can reduce the encroachment of woody species onto tundra (Christie et al., 2015; Speed et al., 2012; Olofsson et al., 2009). Grazing by caribou and muskoxen can reduce the biomass of deciduous shrubs *Betula nana* and *Salix glauca* (Post and Pedersen, 2008), and similar effects have been described for small mammals in warming experiments (Kaarlejärvi et al., 2015). Models incorporating both herbivory and climate change predict that in a warmer climate, where herbivores are abundant, evergreen shrubs will have an advantage over more palatable and widely consumed deciduous shrubs (Yu et al., 2017). However, herbivores may not be able to control shrub expansion everywhere (Morrissette-Boileau et al., 2018) and regional differences are controlled by a complex set of mechanisms that depend on the identity of the shrub and herbivore species, and herbivore density (Christie et al., 2015; Bråthen et al., 2017).

Large herbivores can also buffer the destabilizing effects of warming on tundra plant communities (Post, 2013; Kaarlejärvi et al., 2017) and increase the resilience of tundra ecosystems to warming (Olsen and Klanderud, 2014; Kaarlejärvi et al., 2015). For instance, by selectively consuming certain species, herbivores can mitigate the declines in plant species richness associated with warming, and help maintain plant diversity (Kaarlejärvi et al., 2017). Similarly, other warming-related changes in tundra ecosystems, including carbon dynamics (Väisänen et al., 2014; Cahoon et al., 2012) and climate feedbacks (Cohen et al., 2013) can also be counteracted by herbivory. Thus, grazing management has been proposed as a strategy to moderate some of the effects of warming on tundra ecosystems (Biuw et al., 2014; Bråthen et al., 2017), at least locally. Intense reindeer grazing during summer can reduce ground heating during the snowmelt period (Cohen et al., 2013) and decrease latent and sensible heat fluxes during the growing

season (Te Beest et al., 2016). Similarly, a more diverse herbivore assemblage could be more effective in buffering the effects of climate change on tundra ecosystems, so there is some potential in increasing the diversity of large herbivores in arctic systems through rewilding to preserve arctic vegetation in the future (Olofsson and Post, 2018).

Increased temperatures will also affect the timing of life history events, phenology, which is a critical aspect of trophic interactions in highly seasonal environments like the Arctic. Summers in the tundra are short, so animals have a narrow time window to reproduce and rear their young. A lack of synchrony between the periods when herbivores have high demands for resources and the periods when high-quality food is available can reduce the reproductive success and recruitment of herbivores (Post and Forchhammer, 2008; Doiron et al., 2015) (Box 2). Phenological mismatches are frequent in migratory species, such as geese (Lameris et al., 2017) or caribou (Post and Forchhammer, 2008), because the timing of migration from wintering areas may not be cured by the same drivers or change to the same extent.

Human Management

Climate change alone provides an incomplete explanation for the observed changes in arctic vegetation. For instance, the changes in abundance and distribution of woody plants in the Arctic do not always coincide with recent warming trends (Myers-Smith et al., 2015). The legacies of human activities also contribute to vegetation change in the Arctic (Normand et al., 2017). In parts of Northern Fennoscandia, forest range expansion that had been attributed to climate change is now considered to be the product of regrowth after the gradual abandonment of transhumance activities (Speed et al., 2010a).

Human activities, through hunting and herding can influence herbivore pressure in the Arctic. For example, prehistoric human hunting together with changes in climate likely drove many large herbivores to extinction in the Arctic (Nogués-Bravo et al., 2013), resulting in the species-poor assemblages of large herbivores we see today (Olofsson and Post, 2018). The extinction of these megaherbivores likely contributed to vegetation changes from a graminoid dominated steppe to a higher abundance of woody species (Zimov et al., 1995; Willerslev et al., 2014). Current management policies for large-bodied herbivore populations vary across the Arctic, and this is likely to have large impacts on tundra ecosystems. For example, in Northern Fennoscandia differences in reindeer herding practices between countries, from seasonal migration to sedentary regimes, have led to distinctive differences in vegetation and ecosystem function (Box 3).

Changes in land use beyond the Arctic region can also affect plant-herbivore interactions in the Arctic. For example, the extensive use of fertilizers and other crop management activities in agricultural areas on the southern wintering grounds has contributed to a rapid increase in populations of many Arctic breeding geese (Abraham et al., 2005). These increases in herbivore populations can result in large scale destruction of vegetation (Jefferies et al., 1994). For example, pink footed geese (*Anas brachyrhynchos*) in Svalbard cause extensive soil disturbance through belowground feeding early in the season, causing a reduction of C stocks in arctic tundra (van der Wal et al., 2007). Lesser snow geese have had a similar impact on coastal salt-marshes in Hudson Bay (Jefferies et al., 2006).

Box 2 Migratory geese and trophic mismatch in the Arctic

Warming has been associated with a rapid advancement of the onset of spring in terrestrial Arctic ecosystems (Høye et al., 2007; Post et al., 2009) and earlier plant phenology (Prevéy et al., 2017), but herbivores may not be able to adjust their breeding phenology to compensate these changes in the timing of high-quality food plants (Doiron et al., 2015). Increasing temperatures in the Arctic, with warmer springs and earlier snowmelt, will advance and shorten the peak of nitrogen-rich forage at the breeding grounds (Doiron et al., 2015; Lameris et al., 2017). However, phenology will not advance simultaneously in the Arctic and in the temperate regions along their migratory flyway. Led by environmental cues at their wintering areas, migrating geese will arrive to their Arctic breeding grounds too late (Lameris et al., 2017). Geese are only partially able to adjust their breeding phenology to compensate for annual changes in the timing of high-quality food plants, leading to mismatches of up to 20 days between the two (Doiron et al., 2015). This combination will likely decrease goose reproductive success under climate warming by reducing growth and survival of goslings after hatching (Doiron et al., 2015).

Box 3 Herding can substantially increase grazing pressure

The effects of human management on arctic vegetation through herding of reindeer are evident in the Fennoscandian tundra. A fence was built between Finland and Norway in the 1950s to prevent reindeer crossing the state border. On the Finnish side grazing occurs year-round, while in the Norwegian side grazing is limited to some periods outside the summer, during winter or in the spring/autumn migration. Differences in management across the fence have caused large differences in vegetation: summer grazing by reindeer significantly reduces woody vegetation cover (Olofsson et al., 2009; Bråthen et al., 2017), so vegetation in summer pastures is shorter and less abundant than in winter pastures (Cohen et al., 2013). The higher herbivore pressure due to summer grazing in the Finnish side has reduced the height and abundance of willows in favor of graminoids (Kitti et al., 2009). A remote-sensing study the two sides of the fence showed that grazing-induced vegetation changes resulted in differences in albedo dynamics (Cohen et al., 2013). The shorter and sparser vegetation on the Finnish year-round pastures results in delayed snow melt, increased surface albedo and decreased ground heating during the snowmelt season (May–June), compared to Norwegian pastures.

Future Directions

Herbivory is an active field of research in arctic ecosystems, but there are still many gaps. For example, we still know relatively little about background invertebrate herbivory in tundra. Recent estimates indicate that background herbivory is ubiquitous across the tundra biome and occurs at low intensity, but is likely to increase significantly with arctic warming (Barrio et al., 2017). Similarly, changes in plant chemistry and how they will affect plant-herbivore interactions in a warmer future deserve further investigation. For example, phenolic compounds are expected to decrease with increased temperature (Stark et al., 2015a,b), but the response to warming might differ depending on what type and combination of secondary metabolites plants have (Graglia et al., 2001).

One of the main limitations in our current knowledge of arctic herbivory is the large context-dependency of the results of single-site studies (Bernes et al., 2015). Many factors can modulate how plants respond to herbivores, and how herbivores respond to altered food availability. Being able to generalize the results of herbivory studies in the North will let us generate more robust predictions of the consequences of the rapid ongoing environmental changes in this region (Soininen et al., 2018). This is particularly true for vast and remote areas like the Arctic, where difficult access usually implies unequal sampling efforts (Metcalfe et al., 2018). Coordinated research efforts and the development of theoretical frameworks can help move forward. For example, the concept of functional traits and functional groups is broadly used in arctic plant ecology (Chapin et al., 1996) and has been used for invertebrate herbivores elsewhere (Deraison et al., 2015), and could be a promising approach to generalize the effects and responses of arctic herbivores. Identifying key functional traits of herbivores that mediate their impacts on arctic ecosystem structure and function, such as body size (Legagneux et al., 2014), is thus a first step forward.

One of the challenges when studying plant-herbivore interactions is the design of studies that match sampling of two organisms that occur potentially at different scales, and the need of long term observations to detect trajectories of change in slowly responding tundra plant communities (Olofsson et al., 2013). In some sites, herbivore exclusion triggers rapid changes in vegetation (Falk et al., 2015), whereas in others a time scale of 10 years is not enough to observe a major shift in vegetation (Gough et al., 2008). However, long and short term responses can be qualitatively and quantitatively different because they can be driven by different mechanisms and processes (Väisänen et al., 2014). Similarly, increasing or decreasing herbivore densities may not lead to the same effects on vegetation (Olofsson, 2006) and aspects like the history of grazing need to be taken into account (Väisänen et al., 2014).

Different types of studies and methodologies have been used to study plant-herbivore interactions in the Arctic, ranging from observational studies quantifying signs of herbivory or herbivore activity, to experimental manipulations of herbivore densities or simulated herbivory (Soininen et al., 2018). As well, various remote-sensing techniques using satellite observations have been used to detect large-scale changes in vegetation in areas with different management (Cohen et al., 2013) or following a peak in small mammal abundance (Olofsson et al., 2012). Harmonizing research efforts will help make more robust generalizations across sites and plant-herbivore systems (Barrio et al., 2016b). International research networks, like the Herbivory Network (<http://www.herbivory.lbhi.is>) are promoting such coordinated research efforts that will ultimately improve our understanding of the role of herbivory in these systems.

Glossary

Atmospheric boundary layer This is the lowermost level of the atmosphere where interactions with the surface strongly affect the properties of the air. In the Arctic it can range from just ten meters to several kilometers deep. It is characterized by the presence of turbulence which acts to mix the air and facilitate the exchange of particles, water and heat between the surface and atmosphere.

Surface inversion Defined as when the air close to the surface, in the lowest tens of meters, is thermally stably-stratified i.e., the air above is warmer than the air below. They typically extend from the surface up to a few tens or a couple of hundred meters.

Arctic amplification This is the phenomenon that the Arctic warms more rapidly than the global-average in response to a change in radiative forcing e.g., from the increase in concentration of greenhouse gases.

Abstract

The climate of the high Arctic is unique, and one of the most sensitive to ongoing global change. It is shaped by a strong seasonal cycle which ensures much of the land surface remains snow covered for a large part of the year. Large areas of the land are also covered in permafrost where the ground is either permanently or seasonally frozen. This defines many of the key features of the climate in the high Arctic from the seasonal cycle in air temperature to the hydrology and surface water availability. The sensitivity of the Arctic climate is not just important locally, but also to the global climate system. Many of the largest climate tipping-points that have been identified are located in the high Arctic. Two of the most important tipping points are associated with the irreversible release of carbon dioxide and methane from melting permafrost. The Paris agreement set the target of limiting global warming to less than 2°C in part because this was identified as the level of warming at which we expect these permafrost tipping points to be reached.

Essential Features of the Arctic climate

The Arctic is generally defined as the region of the globe north of the Arctic circle, which lies at approximately 66 °N. This marks the boundary at which in mid-winter the sun does not rise above the horizon, and at mid-summer the sun does not set below the horizon. The most defining feature of the Arctic climate is the strong seasonality in sunlight that reaches the surface. It is this strong seasonality in insolation (incoming solar radiation) that drives the large seasonal cycle in surface temperatures in the Arctic. In the winter the surface receives very little or no insolation and cools radiatively to space. The only source of heat is the intermittent advection of warm and moist air from the lower latitudes and from open water in the Arctic ocean. However, it is worth noting that many features that are often associated with an Arctic climate, such as the presence of permafrost, can be found far south of the Arctic circle.

Fig. 1 shows the climatologies of the annual mean, January (coldest month) and July (warmest month) surface air temperature in the Arctic. The visual separation between temperatures above and below the freezing point of water is deliberately emphasized because in the annual-mean this line indicates where there is some amount of permafrost cover. These figures clearly illustrate how Scandinavia and western Russia have much milder winters compared to the same latitude in the interior of Russia. This is due to the Gulf Stream which brings warm water to northern Europe, triggering the advection of warm, moist air across these regions. In contrast, in North-East Russia there is relatively little advection of warm air from lower latitudes and the winter air temperatures can average below −30°C. A similar pattern of a relatively warm West coast can be seen in the winter over the North American continent.

Fig. 1 The climatology of the (A) annual mean, (B) January, and (C) July surface air temperature over the period 1979–2018. Data are from the ERA5 reanalysis.

In contrast to the winter pattern, the peak summer surface air temperatures are much more homogenous across continents and are determined more by latitude (and hence the amount of solar radiation reaching the surface) and local topography than by large-scale circulation patterns.

We can see from Fig. 1 that a large part of the Arctic land surface is underlain by permafrost. Permafrost forms when the annual average temperature is below the freezing point of water (0°C) for an extended period. The characteristics of permafrost therefore define the surface climate across much of the Arctic. Permafrost is defined as ground that is frozen year-round but typically has a shallow active layer which is seasonally thawed. Below the active layer is the permafrost layer where the ground is perennially frozen. The depth of this perennially-frozen layer is limited by the geothermal gradient in the ground, whereby the temperature increases with depth, and so at some critical depth the ground becomes perennially thawed. The seasonal freezing at the surface is what allows the surface air temperature to drop to such cold temperatures in January in these regions (Fig. 1). In the very dry air of the permafrost regions the surface and air can rapidly cool.

Accompanying this seasonal cycle in surface air temperature is a large seasonal cycle in snow cover. In the winter months much of the Arctic region is covered in snow, although the depth of snow cover is highly heterogenous due to the frequency and intensity of

precipitation, local topography, and the redistribution by wind. The heterogeneity of snow cover can now be reliably obtained from satellite remote sensing products (Rittger et al., 2013). The presence of snow creates a strong intra-seasonal feedback loop on the surface air temperature (Hall, 2004). Snow has a much higher albedo than exposed ground and so a snow-covered region is slower to warm in spring than is a region of bare ground. This means that in those winters with more extensive snow cover, there tends to be a cooler spring as it takes longer for the air to warm, given the same amount of solar radiation. This is because a larger fraction of the available energy from the solar radiation goes to melting snow, rather than warming the air. This feedback can persist even once the snow has melted: as the snow melts more water is added to the soil, and a higher moisture content in the soil also reduces the amount of solar radiation that goes to warming the air.

The climate of the high Arctic is strongly affected by the presence of the Arctic Ocean and the presence of sea ice. The ocean has a much higher heat capacity than the air and the temperature of sea water never drops below -2°C . Therefore, the land surrounding the Arctic ocean is strongly constrained towards this temperature when the water is exposed, i.e., when there is no sea ice. The strong seasonal cycle in surface air temperature drives the seasonality of sea ice cover in the Arctic. But there are also strong feedbacks between the amount of sea ice cover and the surface air temperature, both within the seasonal cycle and interannually (Robock, 1980). When sea ice forms it cuts off the supply of heat from the relatively warm ocean to the colder atmosphere. This allows the atmosphere to cool even further, enhancing the growth of sea ice. These thermal feedbacks are slower in the ocean due to the much higher heat capacity of water than air, and so there is a lag between the peak surface air temperature (July) and the minimum in sea ice extent (September), and correspondingly between the minimum surface air temperature (January) and the maximum in sea ice extent (March). The climatology of the sea ice cover in the annual mean, and at the seasonal maximum and minimum are shown in Fig. 2.

An important feature of the Arctic climate is the presence of atmospheric thermal inversions close to the ground (Bradley et al., 1992; Zhang et al., 2011). These form when the surface cools radiatively to space and the near-surface air becomes cooler than the air above. This creates a stable stratification that suppresses turbulent mixing in the air as buoyancy forces act to stop the air from mixing. This stable stratification can be very strong with temperature differences of up to 5°C in the lowest ten meters of the atmosphere. Such stable stratification is referred to as a surface inversion, and these inversions are an important characteristic of the Arctic atmosphere. They are also a common feature in the Arctic. Fig. 3 shows the frequency of occurrence of these inversions and we can see they occur more than half the time inside much of the Arctic circle (Esau et al., 2012). These surface inversions lead to a high degree of spatial heterogeneity in surface temperatures with even small differences in elevation having a large effect on the surface air temperature. This makes the Arctic surface climate highly heterogeneous. The presence of surface inversions is the principle reason why the Arctic has been warming at around twice the rate of the global average; a feature referred to as Arctic amplification.

Arctic Amplification

The Arctic is a region particularly sensitive to changes in thermal or radiative forcing, for example from an increase in atmospheric greenhouse gas concentrations. In recent decades we have seen the Arctic warm at more than twice the rate of the global-average temperature (Johannessen et al., 2004; Serreze et al., 2009; Serreze and Barry, 2011). This enhanced warming in the Arctic is referred to as Arctic amplification and it is not a new phenomenon. Arctic amplification has been observed as far back as the early part of the 20th century, during the so-called “early warming period,” but the signature of Arctic amplification has also been seen in proxy records going back 1000s of years (Miller et al., 2010).

Fig. 4 shows the amplitude of Arctic amplification over the last century, as defined by the difference in the temperature anomaly in the Arctic ($>66^{\circ}\text{N}$) and in the Northern Hemisphere as a whole (Davy et al., 2018). The data are taken from two records of gridded observations, i.e. station data which has been homogenized and interpolated onto a regular grid. There were relatively few observations from inside the Arctic circle during the early 20th century, and so there is some uncertainty regarding the strength and spatial extent of this early Arctic amplification. While the early warming period was primarily driven by low frequency natural variability in the climate system (the approximately 70-year period cycle of the North Atlantic Oscillation), the current Arctic amplification is likely driven by a combination of this and other sources of natural variability and further enhanced by the buildup of greenhouse gases in the atmosphere (Bengtsson et al., 2004; Wood and Overland, 2010).

The magnitude of Arctic amplification has a strong seasonal cycle. While there is some signature of Arctic amplification in the spring and autumn seasons, it is strongest in winter (Davy et al., 2018). In comparison, during the summer the melting of sea ice keeps the surface air temperature over the ice at constant temperatures near 0°C . So even if heat is added to the system, the surface air temperature does not increase much above this value. Instead, the extra heat enhances the melting of ice. However, increases in the melting of ice have consequences for the rest of the seasonal cycle, leading to a delay in the re-freezing, or simply a reduction in the amount of ice formed in the following winter (Serreze and Francis, 2006).

There are many explanations in the literature for Arctic amplification. These include the sea ice-albedo feedback (Curry et al., 1995; Screen and Simmonds, 2010), snow-albedo feedback (Hall, 2004), atmospheric and oceanic advection, lapse-rate feedback and the presence of persistent surface temperature inversions (Pithan and Mauritsen, 2014). The sea ice-albedo feedback is caused by the much lower albedo of open water compared to that of sea ice. As the Arctic warms, the extent of sea ice is reduced, exposing more of the open water underneath to incoming solar radiation. Since the open water has a lower albedo, more solar radiation is absorbed, enhancing surface warming. While the heat stored by the absorption of solar radiation is built-up in the summer, its effects are principally seen in winter when there is the largest difference between the temperature in the ocean and in the air,

Fig. 2 The climatological mean of the fraction of sea ice cover for the (A) annual mean (B) seasonal maximum in March and (C) the seasonal minimum in September over the period 1979–2018. Data are from the ERA5 reanalysis.

and so a large amount of heat can be transferred from the ocean to the atmosphere. The snow-albedo feedback is caused by changes in the surface area of the Arctic covered in snow in winter. If the amount of snow cover in a given month slowly decreases over the years due to a general warming trend, then the lower albedo of the surface due to the reduced snow-cover results in more radiation being absorbed at the surface and hence more surface warming.

While these feedback processes play an important role in amplifying climate change in the Arctic, surface inversions in the atmosphere are the primary reason for Arctic amplification. Extra heat that gets added to the climate system at the surface, either through changes to the radiation balance or directly through thermal forcing, gets trapped in a thin layer of air close to the ground by the surface inversion. This means that heat added to the Arctic system causes a disproportionately larger change in air temperature here than in the tropics, because the extra heat is spread through a smaller volume of air (Davy and Esau, 2016).

The overall global warming trend is not just asymmetrical in space as exemplified by Arctic amplification, but also in time. Despite the overall global warming trend, there are some regions and times which have seen local cooling in recent decades due to changes in large scale atmospheric circulation patterns or other sources of natural variability. One of the most prominent examples of this is the winter time cooling trend that was observed over continental Asia from the mid-1980s through to the early

Fig. 3 The fraction of days with a surface-based inversion, defined as days with a negative average surface sensible heat flux over the period 1979–2018. Figure reproduced from Esau, I., Davy, R. and Outten, S., (2012). Complementary explanation of temperature response in the lower atmosphere. *Environmental Research Letters*, **7**(4), p.044026.

Fig. 4 Observed Arctic amplification over the period 1910 to 2005 as defined by the difference between the annual-mean temperature anomaly in the Arctic and the northern hemisphere. Data are from the Hadley center (*blue*) and the NASA GISS (*orange*) gridded observations, smoothed using a 21-year running mean.

2000s (Cohen et al., 2012). This has been shown to be related to the loss of sea ice in the Barents and Kara seas, although causal relationships have yet to be demonstrated. Nevertheless, there is a large amount of inter-annual variability in the Arctic climate compared to other regions, and this is partly due to the strong influence of large-scale circulation patterns which also exhibit inter-annual variability. This high level of variability can mask some of the long-term changes in the Arctic climate system.

Consequences of Arctic Amplification

The strong Arctic amplification means that air temperatures in the Arctic have increased by more than 2°C over the last 40 years. This has wide ranging consequences for the Arctic climate. One of the most important implications is the effect of this rapid warming on

permafrost. Observations from the last few decades show that there has been a retreat in the surface area covered by permafrost and a deepening of the active layer in permafrost regions (Kane et al., 1991; Åkerman and Johansson, 2008). While historically the Arctic has acted as a net sink of atmospheric carbon dioxide, studies of carbon fluxes from regions with marginal permafrost indicate that this could switch as permafrost melts and soil that was previously frozen year-round becomes biologically active (Zimov et al., 2006; Schaphoff et al., 2013; Schaefer et al., 2014). In addition to being a source of carbon dioxide, there are also large quantities of methane frozen in permafrost. Methane is a much more potent greenhouse gas than carbon dioxide, although it has a much shorter lifetime in the atmosphere. Therefore, the release of methane into the atmosphere may accelerate climate change in the short term, further supported by these positive feedbacks (Walter et al., 2007). Together, the release of methane and carbon dioxide make up two potentially very large positive feedbacks for climate change. Estimating the magnitude of these feedbacks is an important and ongoing topic of research.

Another important tipping point in the high Arctic is the melting of the ice on land, especially Greenland (Lenton, 2011). In the early 2000s a tipping point was identified in the rate of melting of the Greenland ice sheet, mostly due to increased discharge from glaciers in the southeast and northwest of Greenland (Velicogna and Wahr, 2006). This has fueled a great deal of research into determining the effects this has on the climate system, both locally and for the region as a whole. However, a recent increase in the melt-rate of the ice sheet has been observed, leading to increased river discharge and to flooding (Bevis et al., 2019).

Additionally, the rapid warming in the Arctic has meant that wildfires are now more common and are expected to increase in the future (Hu et al., 2015). These fires affect the climate system in various ways. There are the direct impacts: they release a large amount of carbon dioxide into the atmosphere (Mack et al., 2011) which further contributes to global warming (estimated to be 5%–10% of annual emissions); the aerosols emitted from fires can have a cooling or warming effect, depending on their radiative properties, lifetime in the atmosphere, and interaction with other components of the climate system (Kim et al., 2005). Fires also damage or destroy the vegetation that would otherwise absorb atmospheric carbon dioxide, reducing the natural sink of atmospheric carbon. But there are also numerous indirect effects of fires on the climate: the emission of greenhouse gases from decomposing wood in the wake of fires can often exceed the direct emissions from the fires; new-growth of plants after fires can absorb large quantities of carbon dioxide; these new-growth plants tend to have a higher albedo, and so reflect more sunlight and have a cooling effect, compared to old-growth plants. Therefore the net effect of wildfires on the climate system is therefore very difficult to quantify and remains a topic of ongoing research. It requires a thorough understanding of the physical and chemical processes in the atmosphere, biosphere and land-surface (Randerson et al., 2006).

Future of the Arctic Climate

All climate model projections predict that in the coming century the Arctic climate will change more than any other region on Earth. The amount of warming principally depends upon the concentration of carbon dioxide in the atmosphere—the estimates of emissions of carbon dioxide from human activity over the next century are the largest source of uncertainty in modeling how Arctic climate will change over the next 100 years (Overland et al., 2014). However, there is also a lot of uncertainty in these projections related to the strength of feedback processes present in the Arctic, and in our understanding and ability to model the physics, chemistry and biology of the Arctic climate system (Hodson et al., 2013).

However, even if we manage to keep global mean warming to under 2°C, in keeping with the Paris agreement, this will likely mean more than 3°C of warming in the Arctic, due to Arctic amplification. Even this ‘limited’ warming scenario will therefore lead to major changes to the Arctic climate. At this level of warming we can expect the Arctic ocean to be completely free of sea ice in one out of every ten years. This will have a profound impact on the surrounding land, leading to an increase in cloud cover and precipitation, including rain. This warming will also lead to a further reduction in the extent of permafrost with all the associated effects described earlier (IPCC Special report on 1.5°C warming, 2018).

Despite the projected warming for the Arctic, there are some key features of Arctic climate that will remain constant or change little in the future. These are primarily related to the seasonal cycle in solar radiation. The amount of cloud cover can substantially alter the amount of solar radiation reaching the surface, and we can expect significant changes to the cloud cover, driven by the loss of sea ice and to changes in large-scale circulation patterns (Abe et al., 2016; Screen et al., 2018). However, these changes are only relatively small compared to the magnitude of the seasonal cycle which will continue to dominate the features of the climate in the high Arctic.

Micro-Climates

An important feature of Arctic climate is that in cold climates it is easier to form small-scale micro-climates due to the limited amount of atmospheric mixing that acts to homogenize the air. The physical climate and biological systems are fundamentally inter-linked through numerous feedback processes and this is especially apparent in the Arctic in the formation of micro-climates (Carleton, 2017).

Local topography has a large impact on the formation of micro-climates through topographic influences on surface air temperature, including the effects of katabatic and anabatic winds; slope angle and direction can substantially affect the amount of solar radiation absorbed at the surface and so create strong heterogeneities in the surface climate. Also, in discontinuous permafrost regions the variations in the depth of the active layer due to differences in soil properties can help form small-scale micro-climates.

In addition to these horizontal heterogeneities creating important micro-climates for biological activity, there are also microclimates formed in the strong vertical gradients in climate properties. There can be large temperature differences within the first few centimeters below the surface and small-scale features in the topography (down to the scale of a few centimeters) can lead to large differences in the amount of solar radiation, exposure to wind, temperature and humidity. The differences in these micro-climates can be especially pronounced in winter and spring and so have a large effect on the length of the growing season.

The Urban Arctic

While the Arctic is often perceived as a pristine environment, human activity is leaving an ever-increasing footprint in the Arctic climate system. There are numerous cities within the Arctic circle, and they have a profound impact on the local and regional climate. It has been known for more than a 100 years that the air in cities tends to be warmer than in the surrounding country, an effect referred to as the urban heat island. However, combined data from numerical models, in-situ and satellite observations have recently demonstrated the existence of urban heat islands in the Arctic. The urban heat island effect in mid-latitude climates is principally due to the reduced water availability at the surface which means that more of the incoming energy gets converted into heat rather than being used to evaporate water. However, in the high latitudes a more important effect is the presence of surface inversions. These act to trap the heat from anthropogenic warming close to the surface, leading to temperatures inside cities which can be more than 10°C warmer than in surrounding regions (Varentsov et al., 2018). This effect is exacerbated by the inefficiency in heating and low-quality insulation of many buildings in the Arctic. Most of the cities in the Arctic have been constructed using standards and methods adopted from the more hospitable southern climates. They are constructed quickly to satisfy the immediate needs of an economy focused on mineral and petroleum extraction, without due consideration for the extreme cold. Consequentially, there can be a large amount of residual heat emitted from these buildings. Furthermore, many power stations in Arctic cities use local water bodies for cooling. When emitted from power stations, this water can be tens of degrees warmer than the temperature of water at the intake.

These large temperature anomalies can extend for hundreds of square kilometers around cities and strongly affect the surrounding biosphere. Ironically, these urban heat islands can offer a window into the future for the Arctic climate system.

Ice roads are an important means of connectivity in the Arctic. There is a widespread network of roads servicing the numerous small and large communities in all Arctic nations. The sustained usage of these roads can have important effects on the local climate in the Arctic (Raynolds et al., 2014). The continued use of ice roads across permafrost leads to an artificial compression of the ground underneath the road, while simultaneously raising of height of the surrounding ground. This significantly changes the thermal properties of the soil and can lead to local thawing of the permafrost with many knock-on effects, including the growth of trees. These roads can also act as pathways for invasive species to enter the Arctic as the surrounding environment can offer favorable micro-climates.

The Arctic climate is changing faster than in any other region of the world due to the numerous feedbacks and other processes which amplify the global warming observed over the last century. This is an indirect effect of anthropogenic emission of greenhouse gases and it has already led to an increase of annual-average temperatures in the region of more than 1.5°C. However, the warming caused by the direct effects of human activity in the Arctic can be just as large, with some cities having net annual-average temperature anomalies of 3°C. The implications of these large temperature anomalies on society, infrastructure, and ecology are just now beginning to be understood (Hjort et al., 2018).

Abstract

Vegetation is the basic element of all terrestrial ecosystems, therefore vegetation types are fundamental in the classification of terrestrial biota across all scales, from communities through ecosystems and finally, biomes. The Arctic tundra biome is geographically restricted to a relatively narrow strip around the margins, including the archipelagos, of the Arctic Ocean (Halliday, 2002). The High Arctic Vegetation (HAV) is characterized by low-growing vegetation of low complexity, mostly comprising bryophytes (mosses and liverworts), lichens, small stature vascular plants and algae (micro- and macroalgae) that together constitute the least diverse terrestrial ecosystems in the Northern Hemisphere.

The HAV represents a component of the High Arctic bioclimatic zone and the northern part of the Arctic tundra biome (Thomas et al., 2008; Barry et al., 2013). The main driving factor influencing the complexity and productivity of tundra vegetation is a latitudinal/environmental gradient, based on which the zonal structure of the Arctic biome can be differentiated (Elvebakk, 1999; Walker et al., 2005). According to the Circumpolar Arctic Vegetation Maps, the definition of the High Arctic followed here includes the three northern-most subzones (A—Arctic polar desert; B—northern Arctic tundra; C—middle Arctic tundra), which are distinguished based on botanical and climatic criteria (Elvebakk, 1999; CAVM Team, 2003; Walker et al., 2005) (Fig. 1 and Table 1).

Distribution and Borders

The High Arctic Vegetation has a circumpolar distribution around the highest latitudes of the North American, Greenland and Euroasian coastlines and associated island groups. The spatial diversity of HAV is strongly shaped by island, biogeographic features, as large parts of the High Arctic are comprised of islands and archipelagos. The largest archipelagos, such as the Canadian Arctic Archipelago, Svalbard, Franz Joseph Land, Novaya Zemlya, North Land, and the New Siberian Islands are exclusively occupied by HAV. The total area of the subzones (A–C) comprising HAV is about 2 billion km², of which terrestrial vegetated and non-glaciated land contributes 1.7 billion km² (Walker et al., 2005).

Climatic Distinctiveness

The climate of the Arctic is largely determined by the low solar angles experienced at high latitudes. Differences in photoperiod between summer and winter become more extreme with increasing latitude and result in the 24-h polar day in summer and a polar night in winter. Annually there are only 2–4 months with positive mean air temperatures, with mean temperatures in the warmest month, July, typically being below 5°C and varying between 1°C in subzone A and 7°C in subzone C (Matveyeva, 1998; CAVM Team, 2003; Convey et al., 2018), and an integrated total of 50–350 day degrees above 0°C over the summer. There is, however, a

spatial variation around the High Arctic, in particular with the warming influence of the North Atlantic Current extending as far north as northwest Svalbard.

Precipitation in the High Arctic is generally low, and mostly falls as snow in winter, but amounts increase dramatically from north to south. A good illustration of this gradient is observed for the Baffin Island (the largest island of the Canadian Arctic), over which the total annual precipitation varies from over 200 mm (north) to about 500 mm (south) (Serreze and Hurst, 2000). Spitsbergen and the Taymyr Peninsula receive up to about 400 mm per year, but some northern areas of the High Arctic receive as little precipitation as the Sahara desert, around 40 mm annually (Jonasson et al., 2000). Lack of precipitation can be particularly severe for vegetation during summer, for example in the Kaffiøyra region of north-west Spitsbergen, which receives only 24.5 mm (Kejna et al., 2010). Despite this, the Arctic cannot simply be considered as dry, as low rates of evaporation, high air humidity and snow melt help soils to remain moist during the short summer growth period (Bovis and Barry, 1974).

Plant Biodiversity

The Arctic flora comprises 2218 species of vascular plants (including spore-producing plants (clubmosses—*Lycopodiophyta*, ferns—*Pteridophyta*, and seed-producing plants (*Gymnospermae*, *Angiospermae*)). However, the High Arctic plant diversity is lower and includes about 478 species (102 species in subzone A, 220 species in subzone B, 477 species in subzone C) (Elven, 2011; Barry et al., 2013). There are seven plant species endemic to the High Arctic: *Puccinellia svalbardensis*, *P. gorodkovii* x *Puccinellia vacillans* (sterile hybrid between *Phippsia algida* and *Puccinellia vahliana*), *Saxifraga nathorstii*, *S. svalbardensis*, *Braya humilis* ssp. *ellesmerensis*, *B. glabella* ssp. *prostrata* and *Draba arctica* ssp. *ostenfeldii*. Cryptogamic spore-bearing organisms (lichens, bryophytes, algae) dominate the plant cover of Arctic tundra vegetation (Pointing et al., 2015; Wietrzyk et al., 2016). Their contribution to Arctic vegetation, documented in the most up-to-date flora checklists, includes ca. 900 species of bryophytes, 1860 species of lichens (1610 true lichens, and 250 lichenicolous fungi), and ca. 4000 species of algae (Elven et al., 2011; Meltofte, 2013). Bryophytes and lichens have largest contribution to Arctic tundra plant diversity, (6% and 10% respectively), although their precise numbers of species are not fully known (Lewis et al., 2017). In contrast, vascular plants contribute only 1% of overall Arctic tundra plant diversity.

Vegetation Typology

Arctic vegetation is divided into five bioclimatic subzones (from A—the coldest and most barren, to E—the warmest and most lush and diverse). As noted, only three of these subzones characterize HAV, which is typified by sparse and very low stature vegetation, usually developing on bare mineral soils: A—Arctic polar desert; B—northern Arctic tundra; C—middle Arctic tundra, within which several types of vegetation have been distinguished (Elvebak, 1999; Walker et al., 2005). The most characteristic features of these subzones, along with vegetation types representing them, are presented in Table 1.

Barrens

B1—Cryptogam, herb barren: dominance of cushion forbs and graminoid vascular plants, pronounced occurrence of mosses, liverworts as well as lichens and cyanobacteria.

Dominant vascular plants: cushion forbs e.g., *Papaver dahlianum* ssp. *polare*, *Draba* sp., *Potentilla hyparctica*, *Saxifraga oppositifolia*; graminoids for example, *Alopecurus alpinus*, *Deschampsia* sp., *Poa abbreviata*, *Puccinellia angustata*, *Phippsia algida*, *Luzula nivalis*, *L. confusaa*.

Dominant lichens: species of the genera *Caloplaca*, *Lecanora*, *Ochrolechia*, *Pertusaria*, *Mycobilimbia*, *Collema*, *Thamnolia*, *Cetraria*, *Flavocetraria*, *Cetrariella*, *Stereocaulon*.

Dominant bryophytes: species of the genera *Racomitrium*, *Schistidium*, *Orthothecium*, *Ditrichum*, *Distichium*, *Encalypta*, *Pohlia*, *Bryum*, *Polytrichum*, *Gymnomitrium*, *Cephaloziella*.

Representative syntaxa: *Thlaspietea rotundifolii* (e.g., *Papaveretum dahliani* Hofm. 1968) and *Salicetea herbaceae* (e.g., *Phippsietum algidae-concinnae* Nordh. 1943).

B2—Cryptogam barren complex (bedrock): dominance of saxicolous lichens on bedrock and dwarf shrubs, and fruticose lichens commonly present in areas between bedrock (Fig. 2).

Dominant vascular plants: dwarf shrubs e.g., *Arctous alpina*, *Cassiope tetragona*, *Vaccinium* sp., *Hierochloë alpina*.

Dominant lichens: saxicolous lichens of the genera *Lecidia*, *Lecanora*, *Buellia*, *Porpidia*, *Rhizocarpon*, *Umbilicaria*, *Parmelia*, *Xanthoria*, *Caloplaca*, *Aspicilia*; terricolous lichens of the genera *Cladonia*, *Cladina*, *Flavocetraria*, *Stereocaulon*, as well as the species *Masonhalea richardsonii*, *Bryocaulon divergens*, *Alectoria ochroleuca*.

Representative syntaxa: *Rhizocarpetea geographici*.

B3—Noncarbonate mountain complex: dry acidic tundra complexes occurring on mountains and plateaus with non-carbonate bedrock. Examples include nunatak areas, with many non-carbonate mountain peaks surrounded by glaciers, and plant communities growing on wind-swept, rocky ridges, scree, and dry fellfields, alternating with snowbed plant communities.

Fig. 1 The circumpolar distribution of the High Arctic Vegetation bioclimatic subzones. Subzone A—red, Subzone B—yellow and, Subzone C—green. Modified based on Walker, D. A., Reynolds, M. K., Daniëls, F. J., Einarsson, E., Elvebakk, A., Gould, W. A., Katenin, A. E., Kholod, S. S., Markon, C. J., Melnikov, E. S., Moskalenko, N. G., Talbot, S. S., Yurtsev, B. A. and CAVM Team. (2005). The circumpolar Arctic vegetation map. *Journal of Vegetation Science* **16**, 267–282.

Vegetation changes with elevation in the mountains, forming elevation belts where vegetation is physiognomically similar to that of bioclimate subzones with a comparable summer climate.

Representative syntaxa: *Thlaspietea rotundifolii* (e.g., *Papaveretum dahliani* Hofm. 1968, *Papaveretum radicatae* Dierrss. 1992), *Carici-Kobresietea* (e.g., *Carici-Dryadetum integrifoliae* Dan. 1982 (Ohba 1974)), and *Loiseleurio-Vaccinietea* (e.g., *Cassiopeetum tetragonae* (Bösch. 1933) Dan. 1982).

B4—Carbonate mountain complex: dry calcareous tundra complexes occurring on mountains and plateaus with limestone or dolomite bedrock. Examples again include nunatak areas, with many carbonate mountain peaks surrounded by glaciers, and plant communities growing on wind-swept, rocky ridges, scree, and dry fell-fields, alternating with snowbed plant communities. Vegetation changes with elevation in the mountains, forming elevation belts where vegetation is physiognomically similar to that of bioclimate subzones with a comparable summer climate.

Representative syntaxa: *Thlaspietea rotundifolii* (e.g., *Papaveretum dahliani* Hofm. 1968, *Carici-Dryadetum integrifoliae* Dan. 1982, *Carici-Dryadetum integrifoliae* Dan. 1982).

Graminoid Tundras

G1—Rush/grass, forb, cryptogam tundra: dominance of grasses and rushes occurring in moist tundra on fine-grained, often hummocky soils, also in more protected areas with moderate snow cover. Common presence of cryptogamic crusts composed of cyanobacteria and crustose lichens.

Dominant vascular plants: grasses e.g., *Alopecurus alpinus*, *Dupontia fisheri*, *Deschampsia borealis/brevifolia*, *Poa abbreviata*, *P. arctica*; and rushes e.g., *Luzula nivalis*, *L. confusa*; forbs e.g., *Cardamine bellidifolia*, *Cerastium regelii*, *Minuartia rossii*, *Papaver dahlianum* ssp. *polare*, *Potentilla hyperarctica*, *Saxifraga oppositifolia*, *Ranunculus hyperboreus*, *Draba*, *Stellaria*, *Oxyria digyna*.

Table 1 Characteristics of the High Arctic Vegetation bioclimatic subzones

<i>Bioclimatic subzone (according to Elvebakk, 1999)</i>	<i>Vegetation types (Walker et al., 2005)</i>	<i>Mean July temperature in °C (Matveyeva, 1998)</i>	<i>Sum of mean monthly temperatures > 0° C (Young, 1971, modified by Walker et al., 2005)</i>	<i>Plant cover (Walker et al., 2005)</i>	<i>Plant community structure (Walker et al., 2005)</i>	<i>Number of vascular plant species (Walker et al., 2005)</i>
A—Arctic polar desert	B1—Cryptogam, herb barren (24%) B3—Noncarbonate mountain complex (7%) G1—Rush/grass, forb, cryptogam tundra (19%) P1—Prostrate dwarf-shrub, herb tundra (0.2%) W1—Sedge/grass, moss wetland (1%) Other: glacier areas with nunataks (7%); glaciers (41%)	1–3	<6	<5% of vascular plants ≤40% of cryptogams	Cryptogam layer: < 2 cm tall; single, scattered low vascular plants	<50
B—Northern Arctic tundra	B1—Cryptogam, herb barren (24%) B2—Cryptogam barren complex (bedrock) (0.2%) B3—Noncarbonate mountain complex (13%) B4—Carbonate mountain complex (10%) G1—Rush/grass, forb, cryptogam tundra (17%) G2—Graminoid, prostrate dwarf-shrub, forb tundra (9%) P1—Prostrate dwarf-shrub, herb tundra (11%) W1—Sedge/grass, moss wetland (3%) Other: glacier areas with nunataks (0.3%); glaciers (12%); lakes (0.2%)	4–5	6–9	5%–25% of vascular plants ≤60% of cryptogams	Cryptogam layer: 1–3 cm; herbaceous layer: 5–10 cm; prostrate dwarf-shrub layer: <5 cm	50–100

Summary characteristics for particular vegetation types (from B1 to W1) are given below, following Walker et al. (2005).

Fig. 2 Example of Cryptogam barren complex. © P. Wietrzyk-Pelka.

Dominant bryophytes: *Aulacomnium turgidum*, *Tomentypnum nitens*, *Ditrichum*, *Oncophorus wahlenbergii*, *Polytrichum*, *Racomitrium*, *Schistidium*.

Dominant lichens: species of the genera *Lecanora*, *Biatora*, *Pertusaria*, *Ochrolechia*, *Thamnolia*, *Cetrariella*, *Flavocetraria*, *Stereocaulon*.

Representative syntaxa: *Thlaspietea rotundifolii* (e.g., *Saxifraga stellaris*-*Oxyrion digynae* Gjaerev. 1950), and *Salicetea herbaceae* (e.g., *Luzulion nivalis* Gjaerev. 1950).

G2—Graminoid, prostrate dwarf-shrub, forb tundra: dominance of prostrate dwarf-shrubs and graminoids in plant communities (e.g., *Cassiope tetragona* snowbeds, well-developed mires, and streamside plant communities) occurring in moist to dry tundra on fine-grained, often hummocky near-neutral soils with moderate snow.

Dominant vascular plants: sedges e.g., *Carex misandra*, *C. lugens/arctisibirica/bigelowii*, *C. rupestris*, *Eriophorum triste*, *Kobresia myosuroides*, *C. aquatilis* ssp. *stans*; rushes e.g., *Luzula nivalis*, *L. confusa*; prostrate dwarf-shrubs e.g., *Salix polaris*, *S. rotundifolia*, *S. arctica*, *S. reticulata*, *Dryas* sp.; grasses e.g., *Alopecurus alpinus*, *Puccinellia vahliana*, *P. wrightii*, *Poa arctica*; forbs for example, *Potentilla hyparctica*, *Cardamine bellidifolia*, *Draba nivalis*, *Saxifraga cernua*, *S. hirculus*, *Stellaria* sp., *Pedicularis capitata*, *Papaver* sp.

Dominant bryophytes: *Racomitrium lanuginosum*, *Oncophorus wahlenbergii*, *Campylium stellatum*, *Aulacomnium turgidum*, *Warnstorfia sarmentosa*, *Hylocomium splendens*, *Polytrichum* sp., *Tetralophozia setiformis*, *Anastrophyllum minutum*.

Dominant lichens: *Sphaerophorus globosus*, *Cladina rangiferina*, *Cladonia pyxidata*, *Thamnolia* sp., *Dactylina arctica*, *Flavocetraria* sp., *Masonhalea richardsonii*.

Representative syntaxa: *Carici-Kobresietea* (e.g., *Carici-Dryadetum integrifoliae* Dan. 1982).

G3—Nontussock sedge, dwarf-shrub, moss tundra: dominance of sedges, prostrate and hemiprostrate shrubs, and bryophytes occurring in moist tundra.

Dominant vascular plants: sedges e.g., *Carex arctisibirica/bigelowii/consimilis/lugens*, *C. misandra*, *C. scirpoidea*, *C. membranacea*, *Eriophorum triste*; prostrate and hemiprostrate dwarf shrubs e.g., *Dryas* sp., *Salix arctica*, *S. reticulata*, *S. polaris*, *Arctous rubra*, *Cassiope tetragona*; grasses for example, *Arctagrostis latifolia*, *Deschampsia borealis*, *Poa arctica*; basiphilous forbs e.g., *Bistorta vivipara*, *Silene* sp., *Pyrola grandiflora*, *Senecio frigidus*, *Pedicularis lanata*, *P. capitata*, *Chrysanthemum integrifolium*, *Tofieldia coccinea*, *Lagotis*, *Eutrema edwardsii*, *Astragalus umbellatus*, *Sagina nivalis*, *Saxifraga oppositifolia*.

Dominant bryophytes: *Tomentypnum nitens*, *Hylocomium splendens*, *Aulacomnium turgidum*, *Rhytidium rugosum*, *Ditrichum flexicaule*, *Distichium capillaceum*, *Ptilidium ciliare*.

Dominant lichens: *Thamnolia* sp., *Flavocetraria* sp., *Peltigera* sp., *Dactylina arctica*, *Mycobilimbia lobulata*, *Cladonia pocillum*, *Psoroma hypnorum*.

Representative syntaxa: *Scheuchzerio-Caricetea nigrae* (e.g., *Carici arctisibiricae-Hylocomietum alaskani* Matv. 1994).

Prostrate-Shrub Tundras

P1—Prostrate dwarf-shrub, herb tundra: dominance of prostrate dwarf-shrub communities with presence of lichen and bryophytes occurring in dry tundra (on non-acidic bedrock the dominant vegetation is *Dryas-Salix arctica* communities (Fig. 3), while on acidic substrates it is *Luzula-Salix arctica*).

Fig. 3 Mountain avens (*Dryas octopetala*). © P. Wietrzyk-Pelka.

Dominant vascular plants: prostrate dwarf-shrubs e.g., *Dryas* sp., *Salix arctica*, *S. polaris*, *S. rotundifolia*, *S. phlebophylla*); sedges e.g., *Eriophorum triste*, *Carex rupestris*; rushes for example, *Luzula confusa*, *L. nivalis*, *Juncus biglumis*; grasses e.g., *Alopecurus alpinus*, *Deschampsia* sp.; forbs e.g., *Saxifraga hirculus*, *S. caespitosa*, *S. oppositifolia*, *Novosieversia glacialis*, *Oxytropis* sp.

Dominant bryophytes: *Ditrichum flexicaule*, *Distichium* sp., *Sanionia uncinata*, *Encalypta* sp., *Pohlia* sp., *Polytrichum* sp., *Hylocomium splendens*, *Aulacomnium turgidum*, *Tomentypnum nitens*.

Dominant lichens: *Thamnolia* sp., *Flavocetraria* sp.

Representative syntaxa: *Carici-Kobresietea* (e.g., *Carici-Dryadetum integrifoliae* Dan. 1982) and *Loiseleurio-Vaccinietea* (e.g., *Gymnomitrio-Loiseleurietum* Dan. 1982).

P2—Prostrate/hemiprostrate dwarf-shrub tundra: dominance of hemiprostrate dwarf-shrub communities with presence of lichen and bryophytes (especially communities dominated by *Cassiope tetragona*) occurring in moist to dry tundra on acidic bedrock.

Dominant vascular plants: Prostrate and hemiprostrate dwarf shrubs e.g., *Cassiope tetragona*, *Dryas* sp., *Rhododendron lapponicum*, *Salix arctica*, *S. polaris*; rushes e.g., *Luzula confusa*, *L. nivalis*; forbs e.g., *Oxyria digyna*, *Bistorta vivipara* (Fig. 4), *Silene acaulis*.

Dominant bryophytes: *Aulacomnium turgidum*, *Tomentypnum nitens*, *Hylocomium splendens*, *Sanionia uncinata*, *Polytrichum juniperinum*.

Dominant lichens: e.g., *Peltigera aphthosa*, *Cetrariella delisei*, *Stereocaulon rivulorum*, *Solorina* sp., *Thamnolia* sp.

Representative syntaxa: *Loiseleurio-Vaccinietea* (e.g., *Cassiopetum tetragonae* (Bösch. 1933) Dan. 1982) and *Carici-Kobresietea* (e.g., *Dryado-Cassiopetum tetragonae* (Fries 1913) Hadač 1946).

Wetlands

W1—Sedge/grass, moss wetland: dominance of sedges, forbs, grasses and bryophytes occurring in wet areas and moist elevated microsites.

Fig. 4 Alpine Bistort (*Bistorta vivipara*). © P. Wietrzyk-Pelka.

Dominant vascular plants: sedges e.g., *Carex aquatilis*, *Carex misandra*, *C. membranacea*, *C. atrofusca*, *Eriophorum triste*, *E. scheuchzeri*, *Kobresia simpliciuscula*; forbs for example, *Cardamine pratensis*, *Cerastium regelii*, *Caltha arctica*, *Bistorta vivipara*, *Saxifraga cernua*, *S. foliolosa*, *Pedicularis sudetica*; grasses e.g., *Arctophila fulva*, *Alopecurus alpinus*, *Pleuropogon sabinei*, *Dupontia fisheri*, *Poa pratensis*; shrubs e.g., *Salix arctica*, *S. reticulata*.

Dominant bryophytes: *Calliergon giganteum*, *Warnstorfia sarmentosa*, *Cinclidium arcticum*, *Hamatocaulis vernicosus*, *Campylium stellatum*, *Plagiomnium ellipticum*, *Bryum pseudotriquetrum*, *Tomentypnum nitens*.

Representative syntaxa: *Scheuchzerio-Caricetea* (e.g., *Poo arcticae-Dupontiae fisheri* Matv. 1994, *Meesio triquetrae-Caricetum stantis* Matv. 1994, *Eriophoretum scheuchzeri* Fries 1913 (Fig. 5), *Caricetum rariflorae* Fries 1913, *Arctophiletum fulvae* Thannh. 1976, *Caricetum stantis* Barrett and Krajina 1972).

Zoo-Anthropogenic Disturbed Vegetation

Bird-cliff vegetation: vegetation of open grassy tundra of bird-manured and disturbed cliff vegetation (Fig. 6).

Dominant vascular plants: *Alopecurus magellanicus*, *Cerastium arcticum*, *Poa alpigena*, *Saxifraga cernua*, *S. caespitosa*, *S. hyperborea*.

Representative syntaxa: *Saxifrago cernuae-Cochlearietea groenlandicae* (e.g., *Cerastio arctici-Saxifragion cernuae* H. Hartmann ex Mucina et Daniëls all. nov. hoc loco 2016).

Anthropogenic vegetation: vegetation of open grassy tundra disturbed due to anthropogenic activities and cryoturbation.

Dominant vascular plants: *Cochlearia officinalis*, *Phippsia algida*, *Phippsia concinna*, *Puccinellia angustata*, *Poa alpina*.

Dominant bryophytes: *Leptobryum pyriforme*, *Encalypta mutica*.

Representative syntaxa: *Saxifrago cernuae-Cochlearietea groenlandicae* (e.g., *Cochleariopsion groenlandicae* Hadač 1989).

Fig. 5 *Eriophoretum scheuchzeri* plant community with its dominant vascular plant Polar White Cottongrass (*Eriophorum scheuchzeri*). © P. Wietrzyk-Pelka.

Initial Vegetation

Vegetation developing in deglaciated areas of glacier forelands dominated by lichens, bryophytes, liverworts, and algae.

Progressive retreat of glaciers in the Arctic has been observed since the end of the Little Ice Age, in approximately the mid-19th century (Mann, 2002), and accelerating since the start of the industrial era, and in particular since the mid-20th Century. This on-going process results in the rapid enlargement of ice-free areas in marginal zones of Arctic glaciers, providing new habitat area accessible for colonization by different organisms. These first arrivals are often pioneer cryptogamic species, such as cyanobacteria, lichens, mosses and liverworts. The colonization is typically led by bryophytes, followed by vascular plants and lichens (Wietrzyk et al., 2018). The number of cryptogamic species capable of colonizing freshly deglaciated forelands considerably exceeds that of vascular plants (Wietrzyk et al., 2016, 2017).

Environmental Factors Controlling Vegetation Differentiation

Multiple factors underlie the division of HAV into three large zones (Walker et al., 2005; Jónsdóttir, 2005). These include large-scale geographic patterns in climatic conditions, primarily mean summer temperatures and length of the growing season, as well as the strong influence of warm ocean currents on terrestrial ecosystems, snow cover depth and duration, active layer depth and soil moisture content in summer. Environmental severity gradually increases from zone C to zone A, while the amount of soil organic matter and vegetation cover decrease. Heterogeneity in regional plant communities also results from past glaciation, influenced by time since deglaciation, erosion, and vegetation succession (Walker, 1995).

There are several additional factors that differentiate vegetation within these larger zones, creating a mosaic of unique (micro-) habitats and communities. Among the most important forces, structuring HAV on a landscape scale, are topography associated with temperature and substrate moisture, along with water movement downslope over time, active-layer dynamics, sun, wind and snow exposure (often depending on slope and aspect), and snow depth (Thomas et al., 2008; Convey et al., 2018). Vegetation developing along typical hill-slope toposesquences has been divided into four types (starting from the hill top): open-ridge, zonal, snow-bed, and wet site vegetation (Elvebakk, 1999, Fig. 7). Exposed mountain ridges are usually free from snow and thus subject to strong desiccating winds and extremely low temperatures in winter as well as relatively high temperatures and radiation exposure in summer. Small rosette- and cushion-forming plants and cryptogams, associated with well-drained soil that is poor in organic matter, further suffer from water deficits in summer. In contrast, more amenable sites, such as those associated with late-melting snow beds, are well protected from unfavorable winter weather and buffered from the extreme low air temperatures and exposed ground (Convey et al., 2014, 2018), and have higher water and organic matter content in soil, as well as vegetation cover. However, the growing season in such sites starts later (up to one month) there than in neighboring open areas, which can be a significant limitation to plant growth and development in the short High Arctic summer (Semenchuk et al., 2015, 2016). Moss and graminoid wetlands with 100% ground cover develop in places with the highest continuous water availability (Elvebakk, 1999).

Vegetation growing on slopes may be also disturbed by the mass movement of soil, sediment, and rock triggered by rapid snowmelt, rapid thaw of the active layer or episodic heavy rainfall (Cannone et al., 2010). Vegetation community development and composition depend on rates of colonization and succession. In Ellesmere Island, Canada, this process starts with grasses (*Poa* sp.), then efficient seed producers (such as *Polygonum viviparum*, *Draba* sp.) sporadically became established 2–3 years after landslides occur, and finally woody and semi-woody plants (*Salix arctica*, *Dryas integrifolia*) appear in the community after a minimum of about 10 years. Average total plant cover and species richness generally increase with time after the landslides.

Small-scale differentiation of HAV resulting from microtopography and the action of permafrost is exemplified by patterned ground (Fig. 8). The elevated centres of frost-heave features such as non-sorted circles and polygons are much less vegetated, and sometimes even barren, as compared with their margins and the ground between them (Cannone et al., 2004; Walker et al., 2008). The latter have more protected and stable soils and enhanced water and nutrient availability, which promote plant growth and diversity.

The crucial role of substrate pH cannot be overlooked, as it governs the availability of essential plant nutrients such as calcium and phosphorus, as well as it has wider influence on soil temperature, active layer thickness, photosynthesis, respiration, decomposition rates, and fluxes of trace gases, energy, and water (Elvebakk, 1999; Walker et al., 2005). Local pH variation and gradients are linked with different bedrock types, cryoturbation and glacial history. On a scale of metres or even centimeters, substrate chemistry, including pH, is strongly modified by allochthonous supplies of organic and inorganic compounds originating from the sea, such as those contained in sea spray close to the coast, or deposited in the large amounts of guano in the vicinity of seabird colonies and solitary nests, making these areas outstandingly green and lush oases of life (Euroala and Hakala, 1977; Zwolicki et al., 2013, 2016b; Zmudczyńska-Skarbek et al., 2017; see also Seabird influence subchapter).

Vertebrate herbivores are another biotic agent with the ability to shape specific plant communities in the High Arctic, for example, through the burrowing of rodents, grubbing for roots and rhizomes by geese, trampling, grazing and manuring by reindeer (caribou) and other mammals (Jefferies et al., 1994; Pedersen et al., 2013; Johnson et al., 2011, Fig. 9). The availability of increased nitrogen drives the transition from dwarf shrub, moss and/or lichen-dominated ecosystems to graminoid domination (Johnson et al., 2011).

Additional natural or anthropogenic disturbances can alter HAV at small physical scales, such as detachment of rocks or boulders from cliffs, which destroys parts of the plant communities growing below and promotes damage-resistant and/or fast-growing

Fig. 7 Generalized toposequences for High Arctic Vegetation in A, B, and C bioclimate subzones. Adapted from Elvebakk, A. (1999). Bioclimatic delimitation and subdivision of the Arctic, In: *The Species Concept in the High North: A Panarctic Flora Initiative*, pp. 81–112. Oslo: The Norwegian Academy of Science and Letters.

species (Zmudczyńska-Skarbek et al., 2013). Vegetation patches often develop close to locations of vertebrate dung or the bones of dead animals (Fig. 10), which locally provide an extra source of nutrients. Anthropogenic introduction of alien species is increasingly prominent, especially around human settlements, and because of tourism development (Liška and Soldán, 2004; Ware et al., 2012).

Seabird Influence

In the harsh conditions of the High Arctic terrestrial environment, which generally suffers from chronically low levels of nutrients, seabirds act as bio-vectors transferring nutrients from marine to terrestrial ecosystems, and locally play a crucial role in the development of HAV (Euroala and Hakala, 1977; Elvebakk, 1994; Wojciechowska et al., 2015; Zwolicki et al., 2016a,b). Marine birds feed in the sea and breed on land, often in sizeable colonies where they deposit large amounts of guano (rich in nitrogen, phosphorus and other elements) as well as carcasses and egg shells, which enter the terrestrial ecosystem. As a consequence, the vicinities of seabird nesting sites are characterized by much higher nutrient concentrations, compared to areas beyond the influence of birds (Zwolicki et al., 2013; Fig. 6). This local soil fertilization promotes graminoids and forbs with high growth rates, rapid tissue turnover and low nutrient use efficiencies (e.g., *Poa alpina* and *Cochlearia groenlandica*; Fig. 11). They form lush communities with relatively low diversity, outcompeting slower-growing dwarf shrubs with long-lived leaves and high nutrient use efficiency (e.g., *Saxifraga oppositifolia* and *Salix* sp.) (Wojciechowska et al., 2015; Zwolicki et al., 2016a). The importance of seabird impact is most spectacular in the vicinity of large colonies, but even a single bird carcass could have long lasting influence on vegetation (Street et al., 2018). On a smaller and more scattered scale this phenomenon is also observed in the vicinity of solitary nesting seabirds such as skuas or gulls (Zmudczyńska-Skarbek et al., 2017).

These “bird-cliff” vegetation communities may differ geographically, and are also influenced by differences in bird species diets (plankton-feeders or fish-feeders) and excreta (Elvebakk, 1994; Zwolicki et al., 2013). As a result, bird-cliff vegetation can be

Fig. 10 Vegetation patch developing on and around old whale bones. © P. Convey.

subdivided into subtypes based on the diet of the respective influencing bird colonies, which promote different plant communities (Zwolicki et al., 2016b). Recently observed oceanographic changes in the Arctic, caused by climate warming, are leading to changes in the structure of marine zooplankton communities and may influence the balance between plankton-feeding and fish-feeding seabird populations, and consequently modify the proportion of the bird-cliff vegetation supported by each population (Stempniewicz et al., 2007; Weydmann et al., 2014; Zwolicki et al., 2016b).

Plant Adaptations and Growth Forms

Since the High Arctic flora is young in the context of global evolution, relatively few plant species have adapted sufficiently to survive and propagate in the severe environmental conditions. The “winners” have had to adjust their structure (e.g., plant height and biomass, leaf and root dimensions), water relations (including leaf and root resistance), photosynthesis rates, temperature sensitivity, growth rates, and allocation patterns. Population characteristics, such as density, dispersal, and age structure have also changed in response to selection pressures (Webber et al., 1980; Callaghan, 2001).

Biotic factors that have driven the adaptations of High Arctic flora include interactions between plants, which may provide benefits such as sheltering from wind and abrasion. Decreased water loss is accomplished by possession of tightly-packed shoots, that can also lead to slope stabilization through extensive root systems (Brooker and Callaghan, 1998). Frequent symbiotic associations with mycorrhizae (fungi), and also cyanobacteria, in some species (e.g., *Cassiope tetragona*, *Salix* sp., *Dryas* sp. for mycorrhizae, and mosses; e.g., *Sanionia uncinata* for cyanobacteria) enhance the plants’ nutrient-uptake abilities (Kohn and Stasovski, 1990; Väre et al., 1992; Solheim et al., 1996). Plant-nutrient dynamics are controlled by edaphic limiting factors and, even though locally most higher plants invest a majority of their biomass in roots and rhizomes to increase the surface area for nutrient acquisition, some species also respond to soil nutrient deficiencies by the direct acquisition of soil amino acids (some non-mycorrhizal sedges), or nutrient adsorption through the leaf surface (e.g., some mosses; Skrzypek et al., 2015). Internal nutrient management can be very efficient, for instance keeping low nutrient concentrations in the tissues, producing evergreen and long-lasting structures, and recycling nutrients from senescing to young tissues almost completely. Many plants have to survive periodic anaerobic conditions, for instance when above- and/or below-ground parts become water-logged and frozen during spring and autumn (Crawford et al., 1994). Substrate movement resulting from freeze-thaw cycles further disturbs vegetation development, restricting root development (Jonasson and Callaghan, 1992). In response to physical environmental selective forces, primarily low temperatures (including freezing and freeze-thaw cycles) and solar radiation during the short growing season, plants must develop appropriate physiological and biochemical responses, and many also extend their life cycle from one to 2–5 years. Plant morphology can be an effective means by which plants influence and increase the microhabitat temperatures within which their tissues exist. Compact cushion and mat growth forms are common in HAV. General features of HAV plants include relatively low stature, well-protected buds, long-lived or evergreen leaves, densely aggregated shoots, and limited woody tissues. Different species have evolved different growth forms as strategic adaptations to the demands of varied Arctic habitats. Webber et al. (1980) distinguished ten growth form categories (some of which are also broad taxonomic groups) commonly occurring within the tundra zone, and the classification is valid also for HAV. These are: lichens, mosses, cushion, mat, erect, and rosette forbs (broad leaved herbs), caespitose and single graminoids, and deciduous and evergreen shrubs (see the examples on Fig. 12).

Fig. 12 Examples of High Arctic Vegetation growth forms (based on Webber et al., 1980): *Rhodiola rosea*, cushion forb (A), *Cerastium arcticum*, mat forb (B), *Draba* sp., rosette forb (C), *Luzula* sp., caespitose graminoid (D), *Salix polaris*, deciduous shrub (E), *Cassiope tetragona*, evergreen shrub (F). © D. Kidawa, K. Zmudczyńska-Skarbek, A. Zwolicki.

Anthropogenic Impact

Arctic ecosystems are among the least anthropogenically impacted on Earth, with almost pristine marine and tundra habitats. However, High Arctic ecosystems host a relatively low number of species, connected through simple food webs. Such simplicity makes these ecosystems particularly vulnerable to any environmental change.

Effects of Climate Change

“Latitudinal gradients suggest that arctic plant diversity is sensitive to climate” (Callaghan et al., 2005). The most threatened is probably the High Arctic Vegetation, which occupies the coldest areas and has no possibility of northward dispersal because of the lack of land at higher northern latitudes (Callaghan et al., 2005). Climate is the key ecological factor influencing Arctic terrestrial ecosystems on different time scales, historically and recently.

Recently observed global climate warming, caused predominantly by increasing atmospheric greenhouse gas concentrations, is well documented (IPCC, 2014, 2018). Moreover, instrumental records over the past 50 years show that the Arctic warms faster than areas at lower latitudes. The average Arctic surface temperature has increased by nearly 0.1°C per decade over the past century, causing snow and ice melting, while at the same time, darker land and ocean surfaces absorb more of the sun’s energy, in turn further accelerating the warming of the Arctic. Additionally, relatively warm Atlantic waters, transported northwards with the West Spitsbergen Current, increasingly penetrate more northern parts of the European Arctic which, coupled with the sea temperature rise (Walczowski et al., 2012), intensifies observed changes in the environment. The lower atmospheric layers over the Arctic are shallower than in lower latitudes and thus warm faster, supplied by the increased heat transfer from the ice-free seas to the atmosphere. The amount of energy trapped in the atmosphere, of which only a small part is used in increased evaporation, leads directly to warming, causing a particular threat to Arctic ecosystems (ACIA, 2004; McBean et al., 2005).

The response of Arctic vegetation to contemporary climate warming, similarly as historical responses, is characterized mainly by species relocation rather than adaptation. Changes in populations are influenced by climatic trends and also extreme events, sea-ice decrease and glacier retreat, as well as permafrost and snow cover changes. The soil active layer and coastal permafrost are particularly sensitive to climate warming, which can lead to drastic changes in geomorphology, including major impacts on human infrastructure (Callaghan et al., 2005; Bokhorst et al., 2008, 2011).

High Arctic Vegetation is sensitive to oceanographic and climatic changes, especially to increasing air temperatures in summer. Impacts are apparent in the northern-most Arctic polar desert subzone (A), where mean July temperatures hover near freezing, resulting in changes in plant productivity and species diversity, as well as in shifts in altitudinal and zonal vegetation boundaries. In this case even a small summer warming may lead to a shift towards plant communities that are compositionally and functionally characteristic of more southern subzones (Walker et al., 2008).

Recent remote-sensing records indicate a “greening of the Arctic,” suggesting increased photosynthetic activity and net primary productivity, mostly through shrub expansion (Sturm et al., 2001), although this process is somewhat slower in the High Arctic (Jia et al., 2003). Strong positive relationships between growth and temperature are observed not only in dwarf shrubs such as willows (*Salix* sp.) or Arctic bell-heather *Cassiope tetragona* but also in mosses such as the glittering wood-moss *Hylocomium splendens* (Havström et al., 1995; Callaghan et al., 1997). Additionally, the increasing number of extreme events such as winter warming spikes, tundra fires or surface icing through rain on snow events can also lead to “Arctic browning,” a direct reverse of Arctic greening, which causes drastic declines in vegetation biomass and productivity (Phoenix and Bjerke, 2016).

The main feedback mechanisms between the impacts of climate change on Arctic terrestrial ecosystems and the global climatic system occur through decreasing albedo and increasing release of greenhouse gases, especially methane. Changes in vegetation biomass and structure will have important feedbacks to the permafrost, hydrological cycles, wildlife, and human life. An important aspect of functional changes in tundra soils, driven by warming and drying, is that of their carbon status, which has already changed from a sink to a source, through changes in decomposition and microbial respiration. Moreover, increased carbon dioxide and ultraviolet-B radiation levels affect plant tissue chemistry and are predicted to have long-term impacts on the ecosystem processes that reduce nutrient cycling and have a potential to decrease productivity (Callaghan et al., 2005). Finally, it should be noted that most of the current knowledge on the Arctic floristic evolution and diversity is based on studies of vascular plants. However, it is the relatively poorly studied bryophytes that dominate the High Arctic Vegetation and play a crucial role in global carbon storage and biogeochemical cycles (Lewis et al., 2017).

Other Threats

The impact of direct human activities, such as infrastructure development and exploration for sources of hydrocarbons and minerals, increasingly threaten significant damage to tundra ecosystems. Pollution associated with these activities is a serious threat to the local marine and coastal ecosystems. Construction of pipelines and roads can also physically disturb and fragment habitats and obstruct migration routes. Additionally, as noted above, increased melting of the permafrost can lead to major damage to infrastructure. In parts of the Siberian, Alaskan and Canadian Arctic, erosion following loss of coastal permafrost and fringing sea ice can lead to the loss of up to 100 ft of the coast per year (IPCC, 2014). The vulnerable tundra surface can take years or decades to recover from vehicular tracks.

Air pollution from remote sources at lower latitudes, transported in the upper atmosphere, is being deposited in the Arctic, causing soil contamination and directly affecting organisms. The United Nations Environment Programme has identified the 12 most common persistent global organic pollutants, which are also affecting the Arctic (DDT, heptachlor, texaphene, mirex, aldrin, endrin, dieldrin, chlordane, hexachlorobenzene, PCB, dioxins and furans). Lichens and mosses are particularly vulnerable to air pollution, what is especially important because they serve as significant food sources for many animals, such as reindeer and geese (Arctic Monitoring and Assessment Programme, 1997).

Shipping, resource development corridors, and also tourism are rapidly growing commercial activities in the Arctic. The Arctic cruise industry has rapidly expanded in the past 15 years, and with it the risk of environmental accidents and the introduction of alien species, which may displace native vegetation and impact biodiversity (Stewart et al., 2007; Meltofte, 2013). The well documented reductions in Arctic sea ice, with predictions of an ice-free Arctic Ocean in summer within the next few decades, have led to increasing commercial interest in Arctic shipping, with attendant risks of pollution, accidents, and species movements.

Abstract

This article deals with the mammal fauna of the High Arctic region—the region with the least number of mammal species, outside of Antarctica. The lands of the High Arctic fall between about 70° and 80°N latitude. The vegetation cover is quite sparse and biological productivity at the bottom of the food chain is low, so the terrestrial regions of the High Arctic cannot support large numbers of plant consumers and their predators. These mammals employ a wide variety of strategies and adaptations for cold winter survival, as they are all year-round residents. Unfortunately, the very adaptations that fit mammals for life in the High Arctic may prove to be their downfall as global warming threatens to make their homelands essentially uninhabitable.

Introduction

According to the most recent estimate (Burgin et al., 2018), there are 6400 species of mammals in the world today. Most of these live in the tropical regions, with Brazil ranking first among the nations for greatest number of mammal species (600). The number of mammal species (and most other groups of organisms) decreases toward the poles. This chapter deals with the mammalian fauna of the High Arctic region—the region with the least number of mammal species, outside of Antarctica. As shown in Table 1, the High Arctic region is home to just 45 species of mammals. Of these, 21 (47%) are terrestrial, and 24 (53%) are marine mammals. This proportion of terrestrial to marine mammals is unique to the Arctic. For instance, in North America as a whole, 374 (85%) of the mammal species are terrestrial and 65 (15%) are marine mammals. Why is the High Arctic fauna so different?

The lands of the High Arctic fall between about 70° and 80°N latitude (Fig. 1). The High Arctic is essentially a bitterly cold desert (Fig. 2). If it were not for its polar latitude, this biome could be included in the “Deserts” section of this encyclopedia. An example of the physical environment of the High Arctic can be found in the Zackenberg valley, situated at 74°28′N in northeast Greenland, as described in a study by Westergaard-Nielsen et al. (2017). Here, the mean annual temperature is about −9.0°C. The mean July temperature is 6.3°C and mean February temperature is −19.8°C. As in most High Arctic regions, mean annual precipitation is <250 mm, of which approximately 85% falls as snow. Maximum snow depth is remarkably shallow, ranging from 0.13 to 1.44 m over recent years. In this valley, the growing season is 51 days. This represents the time of year when the ground surface is not frozen, so plants may grow. The vegetation cover is quite sparse in many regions. It grows very slowly and almost all plant species grow very close to the ground, thus avoiding exposure to chilling winds and wind-blown snow and ice crystals. Because biological productivity at the bottom of the food chain is so low, the terrestrial regions of the High Arctic cannot support large numbers of plant consumers and their predators.

One of the best ways of assessing the biological productivity of any ecosystem is its Net Primary Productivity (NPP). NPP is the rate at which atmospheric or aqueous carbon dioxide is converted by primary producers into organic material. Primary production via photosynthesis is a key process within all ecosystems, as the producers form the base of the food web, both on land and in the seas. On land, primary production is mostly carried out by macroscopic plants. In the ocean, primary production is mostly carried out by microscopic phytoplankton.

Gould et al. (2003) studied the vegetation, plant biomass, and net primary productivity patterns of the High Canadian Arctic regions. Their results showed that about 40% of the region has vegetation cover of <5%. About 60% has vegetation cover of 5–50%. Furthermore, about 25% of the Canadian High Arctic has net primary productivity (NPP) of 0–20 g of carbon per square meter per year. The rest of the Canadian High Arctic has NPP of 20–50 g C/m²/year.

Table 1 Mammal species presence/absence in the four High Arctic regions and their IUCN status.

Common name	Scientific name	Canada	Greenland	Svalbard	Russia	IUCN status
Northern pika	<i>Ochotona hyperborea</i>	—	—	—	•	Least concern
Mountain hare	<i>Lepus timidus</i>	—	—	—	•	Least concern
Arctic hare	<i>Lepus arcticus</i>	•	•	—	—	Least concern
Arctic ground squirrel	<i>Urocitellus parryi</i>	•	—	—	—	Least concern
North American brown lemming	<i>Lemmus trimucronatus</i>	•	—	—	—	Least concern
Northern collared lemming	<i>Dicrostonyx groenlandicus</i>	•	•	—	•	Least concern
Arctic lemming	<i>Dicrostonyx torquatus</i>	—	—	—	•	Least concern
Wrangel Island collared lemming	<i>Dicrostonyx vinogradovi</i>	—	—	—	•	Data deficient
Brown lemming	<i>Lemmus sibiricus</i>	—	—	—	•	Least concern
Tundra vole	<i>Microtus oeconomus</i>	—	—	—	•	Least concern
Tundra shrew	<i>Sorex tundrensis</i>	—	—	—	•	Least concern
Gray wolf	<i>Canis lupus</i>	•	•	—	•	Least concern
Arctic fox	<i>Vulpes lagopus</i>	•	•	•	•	Least concern
Red fox	<i>Vulpes vulpes</i>	•	•	—	•	Least concern
Grizzly or brown bear	<i>Ursus arctos</i>	•	—	—	—	Least concern
Polar bear	<i>Ursus maritimus</i>	•	•	•	•	Vulnerable
Short-tailed weasel (Stoat)	<i>Mustela erminea</i>	•	—	—	•	Least concern
Least weasel	<i>Mustela nivalis</i>	•	—	—	—	Least concern
Wolverine	<i>Gulo gulo</i>	•	—	—	•	Least concern
Walrus	<i>Odobenus rosmarus</i>	•	•	•	•	Vulnerable
Hooded seal	<i>Cystophora cristata</i>	•	•	•	—	Vulnerable
Harp seal	<i>Pagophilus groenlandicus</i>	•	•	•	•	Least concern
Harbor seal	<i>Phoca vitulina</i>	•	•	•	—	Least concern
Spotted seal	<i>Phoca largha</i>	—	—	—	•	Least concern
Common seal	<i>Phoca vitulina</i>	—	—	—	•	Least concern
Ringed seal	<i>Pusa hispida</i>	•	•	•	•	Least concern
Bearded seal	<i>Erignathus barbatus</i>	•	•	•	•	Least concern
Ribbon seal	<i>Histiophoca fasciata</i>	—	—	—	•	Least concern
Minke whale	<i>Balaenoptera acutorostrata</i>	•	•	•	•	Least concern
Blue whale	<i>Balaenoptera musculus</i>	•	•	•	•	Endangered
Fin whale	<i>Balaenoptera physalus</i>	•	•	•	•	Endangered
Humpback whale	<i>Megaptera novaeangliae</i>	—	—	—	•	Least concern
Bowhead whale	<i>Balaena mysticetus</i>	•	•	•	•	Least concern
North Atlantic right whale	<i>Eubalaena glacialis</i>	•	•	—	—	Endangered
Beluga whale	<i>Delphinapterus leucas</i>	•	•	—	•	Least concern
Narwhal	<i>Monodon monoceros</i>	•	•	—	•	Least concern
Sperm whale	<i>Physeter macrocephalus</i>	—	•	—	•	Vulnerable
White-beaked dolphin	<i>Lagenorhynchus albirostris</i>	•	•	—	•	Least concern
Atlantic white-sided dolphin	<i>Lagenorhynchus acutus</i>	•	•	—	—	Least concern
Killer whale, Orca	<i>Orcinus orca</i>	•	•	—	•	Data deficient
Long-finned pilot whale	<i>Globicephala melas</i>	—	•	—	—	Data deficient
Harbor porpoise	<i>Phocoena phocoena</i>	•	•	—	•	Least concern
Northern bottlenose whale	<i>Hyperoodon ampullatus</i>	—	•	—	—	Data deficient
Caribou	<i>Rangifer tarandus</i>	•	•	•	•	Vulnerable
Muskox	<i>Ovibos moschatus</i>	•	•	•	—	Least concern

In contrast to the unproductive landscapes of the High Arctic, this region's oceans are significantly more productive. The cold waters of the high latitudes hold more dissolved gases than the warmer waters of the middle and low latitudes. NPP of the High Arctic seas ranges from 35 g C/m²/year in the Western Arctic to 83 g C/m²/year in the Barents Sea (Frey et al., 2016). Of course one of the most limiting factors in Arctic biological productivity, on both land and sea, is the greatly limited seasonality of sunlight. Primary productivity is strongly dependent upon light availability and the availability of nutrients, and thus is highly seasonal in the Arctic region. On land, nutrient availability is essentially limited to the summer season when there is an active layer of thawed soil from which plants may obtain nutrients. In Arctic seas, the melting and retreat of sea ice in spring are strong drivers of primary production. Productivity is particularly high along the continental shelves because the shallow water enhances light availability. Thus, the relatively high NPP of the Arctic Ocean and adjacent seas supports a greater abundance and diversity of mammals than the relatively unproductive High Arctic landscapes.

It is beyond the scope of this review to discuss every High Arctic mammal in detail. Table 2 shows the basic life history information for all species, from the tundra shrew, weighing just 11 g, to the blue whale, tipping the scales at just under 190 million grams. Some of these mammals are remarkably prolific, such as lemmings that produce litters of multiple offspring in as little as

Fig. 1 Map of the northern high latitudes, showing the High Arctic, Low Arctic, and Sub-Arctic vegetation zones (after map by University of Tromsø, Arctic Council).

17 days. Others, such as the whales, reproduce very slowly. This review focuses on a handful of species that show the diversity of strategies and adaptations of the terrestrial mammals that manage to survive in the frozen lands of the High Arctic.

Terrestrial Mammals

All High Arctic terrestrial mammals have one thing in common: they all have to survive the rigors of winter. None of them migrates south during the winter months. Many share common strategies and adaptations. These are grouped into categories, below. Strategies and adaptations used only by carnivores and scavengers are marked with a *star*. Strategies and adaptations used only by herbivores are marked with a *square*. Strategies and adaptations used by both carnivores and herbivores are marked with a *circle*.

- Conserve energy by sleeping most of the time.
- Conserve energy by hibernating (lowered body temperature and metabolic rate).
- Conserve energy by growing a very warm winter coat.

Fig. 2 Photograph of muskox in polar desert on Ellesmere Island. Photo by Christopher Gatto, used with permission.

- Avoid competition with other species for limited winter food resources.
- Optimize ability to extract energy from food.
- Make a hay pile under the snow (herbivores) and defend it from all competitors.
- Eat plants or lichens that are not hidden by the snow.
- Eat plants or lichens buried by snow, but in locations unknown to other herbivores.
- Curl up together in a group nest for shared body warmth.
- Stay beneath the snow most or all of the time (temperatures are much warmer there than in the air).
- Build up a thick layer of fat to get through times of fasting or food scarcity.
- ★ Scavenge the carcasses of other animals that do not make it through the winter.

Small Terrestrial Mammals

Small mammals, such as voles, shrews, pikas and lemmings, have a very large surface-to-volume ratio. This causes them to lose a great deal of heat to the environment during the winter. Not surprisingly, then, the small mammals of the High Arctic avoid exposure to winter air temperatures to the best of their ability. Most of them gain protection from winter air temperatures by tunneling beneath the snow. Snow provides excellent insulation from cold air temperatures. In a study done during a Svalbard winter, [Convey et al. \(2015\)](#) measured ambient temperatures where there was no snow cover, shallow snow cover (30 cm) and deep snow cover (120 cm). Local air temperatures at the study site fluctuated between -3 and -24°C through the study. Where the ground was bare of snow, soil temperatures matched air temperatures closely. Soil temperatures varied less under 30 cm of snow, and did not decrease below -12°C . Temperatures beneath 120 cm of snow were even more stable and did not decline below -2°C . Another key aspect of snow cover is moisture. Tunnels made by small mammals beneath the snow are not only substantially warmer than the air above, they also hold considerable moisture. This relatively warm, moist air helps small mammals avoid both the freezing and desiccation they would face on the surface.

Lemmings

Lemmings are vital to the functioning of many High Arctic ecosystems. They occur in large numbers, reproduce rapidly, and consume large quantities of vegetation. In turn, they are the principal prey of many arctic predators. [Gilg et al. \(2009\)](#) note that the northern collared lemming ([Fig. 3](#)) is the single most important prey of four predators in the High Arctic: the snowy owl (*Bubo scandiacus*), the Arctic fox ([Fig. 4](#)), the long-tailed skua (*Stercorarius longicaudus*), and the short-tailed weasel ([Fig. 5](#)). There are five species of lemmings listed in [Table 1](#). These include the northern collared lemming and the brown lemming, discussed below.

Arctic lemmings all excavate runways at the snow-ground interface. During the short summer months, the northern collared lemming is found on dry, sandy or gravelly habitats on the tundra. Unlike other lemmings, it turns white in winter, and grows elongated claws that help it dig through snow. This species builds extensive runways and nesting areas beneath the snow. Like other lemmings, the northern collared lemming is probably a pure herbivore, eating a variety of plants. Willows and sedges are the dominant plants used as forage by northern collared lemmings in arctic Greenland. Willow leaves provide high quality forage in

Table 2 Life history information for High Arctic mammals. Data from [Animal Diversity Web \(2018\)](https://www.iucnredlist.org/) and the IUCN Redlist (<https://www.iucnredlist.org/>)

<i>Species</i>	<i>Mass</i>	<i>Life span (years)</i>	<i>Gestation (days)</i>	<i>Litter size</i>	<i>Habitat in High Arctic</i>	<i>Diet in High Arctic</i>
Northern pika	120 g	≤ 9	28	3–4	Found on talus and other rocky slopes	Grasses and other herbs; makes hay piles for winter food
Mountain hare	3 kg	9	47–54	1–4	On open arctic tundra	Tundra herbs and forbs
Arctic hare	≤ 68 kg	3–5	50	2–8	Mountainous tundra, rocky plateaus and treeless coasts	Willow, mosses, lichens, buds, berries, leaves, roots
Arctic ground squirrel	≤ 15 kg	8–10	25–30	4	Open tundra (lives in burrows)	Plants, small vertebrates, eggs, carrion
North American brown lemming	58–68 g	≤ 1	23	4–9	Open tundra (lives in burrows)	Feeds on herbs, cotton grass, mosses, lichens, roots
Northern collared lemming	30–112 g	3	19–21	4–8	Open tundra (lives in burrows)	Willow buds, fruits, flowers, grasses and twigs
Arctic lemming	20–30 g	≤ 4	17	5–6	Open tundra (lives in burrows)	Willows, birches, grasses, flowers
Wrangel Island collared lemming	30 g	?	?	3–6	Dry rocky slopes	Willow and birch shrubs, grasses
Brown lemming	45–130 g	≤ 1	21	2–13	Tundra meadows	Grasses, sedges, mosses
Tundra vole	25–80 g	≤ 2	20–21	3–9	Damp, densely vegetated riparian areas	Grasses, sedges, seeds
Tundra shrew	7–11 g	1	13–28?	8–12	River meadows with dense vegetation	Insects, worms, grasses
Gray wolf	23–80 kg	5–13	63	6–7	Wide ranging on all tundra habitats	Eggs, small mammals, caribou, muskox, carrion
Arctic fox	3–8 kg	12–15	46–58	3–8	Often in coastal regions; scavenge on pack ice in winter	Birds, small mammals, fish, eggs, insects, carrion
Red fox	3–14 kg	3–7	49–55	1–9	Open tundra	Birds, small mammals, fish, eggs, insects, fruit, carrion
Grizzly or brown bear	80–250 kg	20–30	180–266	2	Open tundra, coasts	Mammals, fish, carrion, insects, leaves, roots, fruit
Polar bear	150–800 kg	25–30	195–265	1–4	Arctic Ocean pack ice	Ringed seals, bearded seals, hooded seals, harp seals, walrus, sea birds, fish
Short-tailed weasel (Stoat)	25–116 g	1–2	280	4–9	Open tundra	Small mammals, birds, fish, eggs, insects
Least weasel	30–50 g	2–4	35	1–13	Open tundra	Birds, small mammals, fish, eggs, carrion, insects
Wolverine	9–30 kg	5–7	120–272	1–5	Open tundra	Birds, mammals, eggs, carrion
Walrus	600–1500 kg	30–40	331	1	Coastal marine waters; pack ice; beaches	Mollusks, crustaceans, other marine invertebrates
Hooded seal	160–300 kg	30–35	240–250	1	Coastal marine waters; pack ice, beaches	Fish, cephalopods, crustaceans
Harp seal	120–135 kg	20–35	228	1	Coastal marine waters; pack ice; beaches	Fish, crustaceans
Harbor seal	80–170 kg	26–34	253	2	Coastal marine waters; pack ice; estuaries; beaches	Fish, cephalopods, crustaceans
Spotted seal	65–115 kg	29–35	213–365	1	Sea ice in shallow waters	Fish, mollusks, crustaceans
Common seal	80–170 kg	32–40	253	1–2	Shallow marine waters and estuaries	Fish, cephalopods, marine crustaceans
Ringed seal	32–124 kg	15–28	330	1	Marine waters with ice floes and pack ice	Fish, aquatic crustaceans, other marine invertebrates
Bearded seal	200–430 kg	20–25	259	1	Shallow marine waters with ice floes and pack ice	Mollusks, crustaceans, fish
Ribbon seal	72–90 kg	20–30	300–330	1	Deep marine waters with small pack ice	Cephalopods, crustaceans, fish
Minke whale	6000–9000 kg	45–50	300–330	1	< 170 km from shore, well into pack ice	Krill, small fish
Blue whale	≤ 190,000 kg	80–90	330–365	1	Open ocean	Krill, other marine invertebrates
Fin whale	≤ 70,000 kg	75–95	330–365	1	Ocean waters > 200 m deep	Crustaceans, small fish, squid
Humpback whale	30,000 kg	77–95	342	1	Open and coastal waters, well into pack ice	95% fish, krill
Bowhead whale	75,000–100,000 kg	≤ 200	365–488	1	Shallow waters, following receding ice drifts	Crustaceans, zooplankton
North Atlantic right whale	55,000–95,000 kg	50–67	365	1	Often in coastal waters	Copepods, krill, zooplankton

Table 2 Life history information for High Arctic mammals. Data from *Animal Diversity Web* (2018) and the IUCN Redlist (<https://www.iucnredlist.org/>)—cont'd

<i>Species</i>	<i>Mass</i>	<i>Life span (years)</i>	<i>Gestation (days)</i>	<i>Litter size</i>	<i>Habitat in High Arctic</i>	<i>Diet in High Arctic</i>
Beluga whale	1350–1500 kg	25–30	425	1	Inlets, bays, shallow arctic seas, river mouths	Fish, mollusks, marine worms, crustaceans
Narwhal	900–1600 kg	30–55	396	1	In deep water around loose pack ice	Squid, fish, crustaceans
Sperm whale	35,000–50,000 kg	60–70	427–488	1	Deep waters > 1000 m	Squid (esp. giant squid), fish, sharks, skates
White-beaked dolphin	200 kg	?	?	1	Cold, open waters	Fish, cephalopods, crustaceans
Atlantic white-sided dolphin	180–250 kg	22–27	316	1	Cold, open waters > 40 m depth	Fish, mollusks, crustaceans
Killer whale, Orca	4000–7200 kg	36–63	365–547	1	In all marine waters, generally prefer depths of 20–60 m	Seals, sea lions, smaller whales and dolphins, fish, sharks, cephalopods
Long-finned pilot whale	1800–3800 kg	46–60	488	1	In deep and coastal waters	Mollusks (especially squid) and fish
Harbor porpoise	45–60 kg	12–13	335	1	Shallow coastal waters	Fish, cephalopods
Northern bottlenose whale	5800–7500 kg	35–40	365	1	In waters > 1000 m, at or near North Atlantic ice shelf	Squid, fish, benthic invertebrates
Caribou	55–318 kg	5–15	232	1	Open tundra	Leaves, roots, tubers, wood, bark, mosses, lichens in winter
Muskox	180–400 kg	14–20	228–259	1–2	Open tundra	Leaves, roots, tubers, stems, seeds, fruit, flowers, mosses, lichens

the early stages of their annual growth, but protein content and digestibility decline markedly by late summer, whereas sedges remain high in forage quality throughout the growing season. This species prefers to overwinter in willow-dominated communities, and relies heavily on willows for winter food.

Northern collared lemmings average about 12 cm in length and weigh about 40 g. Mating takes place as early as January, but extends through September. Females may have up to three litters per year, averaging 4–5 offspring per litter. Most northern collared lemmings live only 1 year, so there is a rapid turnover of individuals.

Northern collared lemming populations go through boom-and-bust cycles. Ten periods of high abundance and nine periods of low abundance of northern collared lemming took place from 1932 to 1990 in arctic North America. [Pitelka and Batzli \(1993\)](#) documented these lemming population cycles, noting that variations in lemming populations in the Northwest Territories of Canada appear to be related to a variety of factors, including the intensity of cold periods in autumn, the phenology of change from summer to winter morphology, and snow depth. Mild autumn weather and deep winter snow work together to favor high populations of lemmings, whereas cold autumn weather and shallow winter snows cause severe hardships, leading to much lower populations. These lemmings seek out the deepest snow to excavate tunnels leading to nests.

It is clear that global change is altering arctic ecosystems, starting with vegetation cover. There is also some evidence that the boom-bust cycles of arctic lemmings are changing in response to environmental disturbances ([Gill et al., 2009](#)). Because the northern collared lemming is such an important prey species in the High Arctic, any changes in its boom-bust population cycle will have serious impacts on its predators, as well. However, it is extremely difficult to predict the ecological impacts of climate change, because individual species' responses depend on various aspects of their life histories, and the different species in a food web are also affected by interactions between species. The lemming–predator community is one example of these complicated interactions. However, [Gill et al. \(2009\)](#) concluded that predicted climate change will increase the length of the lemming population cycle and decrease their maximum population densities. The smaller booms in lemming population will hurt predator populations because they are adapted to exploit the years of lemming population booms. Climate change may eventually lead to the decline and local extinction of some of these predators. Recent anomalous observations about lack of cyclic lemming dynamics in eastern Greenland may well be the first signs of a severe impact of climate change on the lemming–predator communities in Greenland and elsewhere in the High Arctic.

The brown lemming ([Fig. 5](#)) ranges across most of the Arctic. Brown lemmings also undergo population cycles that run every 4–6 years, though there is no clear pattern to these cycles. Every local population appears to have its own population cycle. Many theories have been put forward to explain lemming population cycles, in fact this topic has seen a lively debate in the ecological literature since Elton began publishing his studies in 1924. So far, theories have linked lemming boom-bust cycles with sun spots, changing weather, social stress, dispersal patterns, depletion of food resources, decline in nutritional content of food, grazing-induced chemical defenses in plants, predation by resident or nomadic predators, parasites, disease, and the structural quality of habitat. No clear answers have emerged, but it seems most likely that a combination of many of the above factors is responsible for the timing and intensity of these puzzling cycles.

Fauteux et al. (2015) recently carried out a study of brown lemming population cycles on Bylot Island (73°N) in the Canadian High Arctic. They recorded population booms during the summers of 2004, 2008, 2011. Their results show that high lemming mortality causes population declines during summer and fall, which suggests that predation is sufficient to cause population crashes, whereas high winter fecundity is the primary factor leading to population booms. They noted a connection between deep winter snow and early summer survival, and suggested that deeper snow cover deters predators. It is still unclear why reproduction remains low during the low phase. Duchesne et al. (2011) also studied lemming predation on Bylot Island. They concluded that predation by short-tailed weasels was more successful where lemmings were concentrated beneath the snow, and that weasel predation was greater on collared lemmings than on brown lemmings. Snow cover did not affect the probability of predation of lemming nests by weasels, but deep snow cover limited predation attempts by arctic foxes. They also concluded that snow cover plays a key role in the spatial structure of wintering lemming populations and potentially in their population dynamics.

Erlinge et al. (2011) studied interactions between brown lemmings and their food plants in northern Siberia in a transect of study sites from the Kola Peninsula to Wrangel Island. Sedges (*Carex*) form an important part of lemming diet in the Arctic. It is known that arctic sedges produce defensive chemical compounds in response to grazing pressure, and that these chemicals affect the foraging of lemmings. In particular, proteinase inhibitors (PI) are produced in response to grazing and reduce the action of the herbivore's proteolytic enzymes. This inhibits the lemmings' ability to absorb proteins from their food. Proteins are essential for animal growth and reproduction. The authors found that when levels of PI were high in the lemmings' food plants, the number of embryos per pregnant female declined significantly. This chemical defense phenomenon is not the only cause of lemming boom and bust cycles, however (Fig. 6). Predator numbers also increase in response to lemming population rises, and then decline as lemming numbers decline. In addition, there is competition within the lemming population for vital resources, such as the best foraging locations. Apparently the more mature females out-compete the younger females for the best feeding locations, and are therefore able to produce more offspring. Of course the criteria for best places for lemmings to feed must include safety from predation. The risk of being caught by predators shapes the foraging habits of lemmings, as is seen from their concentrated grazing close to runways and shelters.

Fig. 6 Lemming-food plant-predator interactions. Concepts from Erlinge et al. (2011).

There are major differences between the diets of the brown and collared lemming (Batzli and Pitelka, 1983). Brown lemmings eat mostly grasses, sedges, and mosses, whereas collared lemmings prefer willow leaves and forbs. Brown lemming diets change with season and habitat. Monocotyledons such as grasses are always the most important food items in winter and in drier habitats mosses became a more important part of the diet. This species of lemming reaches much higher densities than collared lemmings in some regions. They prefer lower, wetter habitats than do collared lemmings. Brown lemmings appear to concentrate in higher habitats during early summer when melt water floods lower habitats, then shift to lower habitats where preferred food is more available as the waters recede. Nearly all patterns of lemming habitat use seemed to be linked to food availability.

Tundra shrew

One of the least-understood small mammals of the High Arctic is the tundra shrew (Fig. 3). This is the smallest mammal of the region, and very little is known of its habits. We do know that shrews are generally insectivores and that their very high metabolic rate dictates that they must hunt for prey almost continuously, night and day. As a group, shrews must consume 80–90% of their body weight daily, in order to survive. We also know that shrews are not able to store significant quantities of fat, so they are not able to hibernate in winter. Thus the great mystery concerning the tundra shrew: how does it survive the Arctic winter, when its prey (insects and other invertebrates) are virtually impossible to find, and cold temperatures place even higher energy demands on its metabolism? Some shrews are able to enter a condition called torpor—a state of decreased physiological activity. But without significant stored body fats, can torpor sustain them through 8–10 months of subfreezing temperatures? Until a scientific study of the life history of the tundra shrew is performed, these questions will remain unanswered.

Arctic ground squirrel

This species (Fig. 4) lives in colonies with an elaborate burrow system. A resident burrow system is used through most of the year. A 30-ha study region on the North Slope of Alaska had 66 resident burrow systems, and each system had between 20 and 50 openings at the surface. The other type of burrow system is used only for breeding. All burrows are dug in well-drained sites with low vegetation (good visibility at burrow openings is essential for predator awareness). Such localities as stream banks, glacial moraines, the flanks of pingos, and beach ridges are used.

Unlike some other arctic rodents, arctic ground squirrel populations do not go through boom and bust cycles. Arctic ground squirrels have an annual activity pattern that varies little from year to year. Hibernation begins in September or early October, followed by emergence between mid-March and mid-April. Real activity does not begin in earnest until snow cover is diminished. Summer foraging includes nightly rest periods, in spite of the round-the-clock daylight of the arctic summer. The squirrels build a substantial layer of fat in preparation for their winter hibernation. Adult squirrels build up about 350 g of fat over a period of 60–70 days prior to hibernation.

Arctic ground squirrel diet includes a wide variety of herbs (over 40 species of plants) and shrubs. Mosses, shrub leaves, meat, and eggs make up about half the squirrels' diet in early summer, while herbs, seeds, and horsetails constitute >80% of their diet in mid- and late summer. These squirrels take eggs from willow ptarmigan nests. They also prey on collared lemmings.

Arctic ground squirrels have come under intense study by biologists in recent years because of their remarkable hibernation physiology. Arctic ground squirrels are perhaps the most extreme rodent hibernator, hibernating up to 8 months of the year at body temperatures below freezing. However, they arouse every 1–3 weeks to elevate body temperature to normal levels for <24 h before re-entering torpor. Unlike some other arctic mammals, arctic ground squirrels do not hibernate communally. Individuals within colonies enter each torpor separately, and remain solitary throughout the winter (Lee et al., 2016). The minimum body temperature (T_b) recorded in ground squirrels was –2.0°C. These squirrels decrease their T_b below freezing to minimize the difference between body and ambient temperatures. They allow T_b to decrease below the ice nucleation point of their tissues and thereby minimize the thermal gradient and rate of heat loss. Richter et al. (2015) found that arctic ground squirrels maintain steady state torpor at ambient temperatures as low as –26°C. They accomplish this through a 36-fold increase in their torpor metabolic rate (TMR), compared to their minimum TMR when ambient air temperatures are at or near freezing.

Large Terrestrial Mammals

In contrast to the small mammals, the large mammals have a far smaller surface-to-volume ratio, so they lose much less internal metabolic heat to the environment. Many of these larger mammals remain active in the arctic winter, such as the polar bear, arctic fox, muskox and caribou. Their exposure to low winter temperatures is not without cost, however. All of these animals lose weight through the cold months. Grazers, including caribou and muskox, must continue to forage for food throughout the year, in order to maintain the gut micro-organisms that are essential to their digestion. Snow conditions are critical to the health and survival of grazing mammals in the Arctic. When snow cover is too deep, many grazers may starve before the end of the winter season.

Caribou

The two grazing mammals of the High Arctic are the muskox (*Ovibos moschatus*) (Fig. 3) and caribou, or reindeer (*Rangifer tarandus*) (Fig. 4). Research on the dietary patterns and overall fitness of these two species in High Arctic populations shows the striking effects of snow cover depth. A study of female barren-ground caribou on Coats Island in the Canadian High Arctic was done by Adamczewski et al. (1988). The population density of caribou on the island was 0.38 animals per km². The population density of this species in subarctic Norway is six times higher: 2.45 animals per km². Of course the carrying capacity of a given region is

closely tied to its NPP. In this study, NPP for Coats Island averaged 50–60 g per m² in mesic and wet meadows, the most productive habitats. Caribou fed almost exclusively in these meadows in summer, and their diet was dominated by willow leaves. During the year of this study, the winter snowpack consisted of hard-packed snow in depths of 50–80 cm on all low-lying vegetation. The caribou were not able to scrape away the snow with their antlers and hooves in the heavily covered lowlands. They were limited to seeking dried vegetation in places where the snow was < 20 cm deep. These shallow snow conditions were found only the slopes of wind-blown ridges and the tops of high-centered polygons. The available forage in these localities was drastically reduced in quantity and quality compared with forage available in summer. During that winter, prolonged deep snow cover killed many calves.

The stomach contents of these animals dropped from a weight of 13 kg per day in August to 8 kg per day in October, and the content changed dramatically, from willow leaves to dried grasses. The weight of stomach contents doubled by March, but the March stomach contents were dominated by highly fibrous foods with low nutritional content. The caribou burned large amounts of body fat and protein from their skeletal muscles to sustain themselves through winter.

The IUCN (2018) currently lists *Rangifer tarandus* as “Vulnerable.” This classification is due to a 40% decline in numbers over three generations (about 21–27 years) across the Arctic. Caribou numbers have declined from about 4,800,000 to about 2,900,000 individuals. There is considerable uncertainty about the under-lying causes of this decline, but one of the chief causes has been habitat changes. In particular, habitat fragmentation has been critical in parts of northern Eurasia, including the establishment of barriers (related to human activities and infrastructure development), which can disrupt migration routes and destroy seasonal habitat. Predicted future warming of climate will certainly bring habitat alterations, and will have exacerbating effects on disease transmission and parasitism including the possibility of epidemics.

While the caribou herds of the High Arctic are not likely to suffer the effects of human-caused habitat fragmentation in the near future, the effects of global warming will be amplified in the High Arctic, potentially causing large-scale changes in vegetation patterns that will affect entire ecosystems, including the grazers.

Muskox

Muskoxen face the same threats of malnutrition in the High Arctic winter. As most northern ungulates, they rely heavily on fat reserves built up over summer and autumn to get them through the snow-covered period. Mosbacher et al. (2016) performed an isotopic study of muskox hair samples to determine the quality of their forage through the different seasons. It is known that nutritional stress is particularly great on adult females that must use body stores of fat to get through pregnancy and lactation, which happen in late winter through spring. The health of muskox herds is thus strongly influenced by the nutritional state of the females. By the end of the rutting season, adult females must replenish their fat reserves to about 20% fat of their body weight in order to mate and bear young. In the summer, muskoxen forage mainly on the energy-rich grasses found in the more productive, wetter habitats. In winter their diet shifts to willows found exposed on barren, wind-swept ridges. Interestingly, this shift from summer diet of grasses to winter diet of willows is the exact opposite of the seasonal grazing pattern of caribou, discussed above. Pregnancy rates can exceed 90% in wild muskox populations, but under less favorable conditions, such as winters with deep snowpack, pregnancy rates decline, and occasionally no calves are born at all.

Gray wolf

For many people, the gray wolf (Fig. 4) is the symbol of Arctic wilderness. Driven to near extinction in most of its former range in the temperate latitudes, the wolf hangs on in the north. Males may reach 65 kg in weight, and full size is attained in the first year of life. This is a highly social animal that lives in packs that include a mated pair, the young of the year, and some yearlings. Pack size ranges from two to as many as 30, although most packs consist of less than 12 wolves. Wolves range widely in search of food. Their home ranges average about 1550 km² in northern Alaska. In the temperate zone where prey is plentiful, wolf home ranges average only about 150 km².

The arctic wolf is a subspecies or race of the gray wolf (*Canis lupus*). Year-around white coats and slightly shorter noses and ears distinguish these wolves from other races of the gray wolf, and the life of the arctic wolf is basically the same as the lives of wolves everywhere. The arctic wolf lives in the area along the northern edge of the North American continent and northward to the North Pole, as well as along the eastern and northern shores of Greenland. Several large islands occupy the region between the north edge of the continent and the Pole. Although ice and snow permanently cover much of the area, parts of these islands become snow free between mid-June and mid-August and support enough low-growing plants to feed musk-oxen, caribou, and arctic hares. These creatures constitute most of the food supply for the arctic wolves. Arctic wolf packs must hunt over vast territories to meet their needs. Many pack territories cover 2600 km² or more. Observations on wolves reveal some common patterns in their hunting habits. Wolves almost always prey on young, very old, and sick animals. Their predation of the latter two groups helps keep herds of grazing mammals healthy. Their predation on the young helps keep prey animal numbers in check.

Little is known arctic wolf movements near the northern extreme of their range in the High Arctic. There, wolves prey primarily on muskoxen and must survive 4 months of winter darkness and temperatures down to –53°C. Mech and Cluff (2011) studied the movements of a pack of > 20 wolves on Ellesmere Island (80°N latitude) using a GPS collaring system on a lead wolf in the pack. They found that the pack traveled 6640 km² from July 2009 to April 2010. This represents the largest wolf range ever reported (Fig. 7). The wolf and presumably his pack once made a 263-km foray in a nine-day winter trek. Ulf (2008) reported that an arctic wolf pack in northeast Greenland once trekked 76 km in 12 h. Interestingly, wolf pack movements during the dark winter months on Ellesmere Island did not differ from those of the rest of the year.

Fig. 7 Map of south-central Ellesmere Island, Canada, showing locations (*red* dots) of a wolf pack tracked by [Mech and Cluff \(2011\)](#) through the winter of 2009–2010. Inset: Map of Ellesmere Island, showing study area (highlighted in *red*).

The limited food resources of the High Arctic affect arctic wolf fitness and reproduction. A study by [Ulf \(2008\)](#) on a wolf pack in northeast Greenland from 1978 to 1998 showed a mean litter size of only two pups per litter. This represents the lowest mean litter size recorded for wolves in North America, where the overall average is 4–6 pups per litter. The most likely cause of these small arctic wolf pup litters is low availability of ungulate prey. However, the larger the wolf pack, the greater the number of pups per litter. Large packs (4–7 adults) produced significantly more pups than smaller packs. Ulf's study indicates that maximum productivity of wolves in Greenland was 58% below that of wolves elsewhere.

A detailed study of arctic wolf diet was carried out by [Dalerum et al. \(2018\)](#). They determined prey items by examining wolf scats collected at three sites in the High Arctic region of Canada and northwestern Greenland. The scats contained 55% arctic hare remains, followed by 39% muskox remains. Study of the available literature on arctic wolf diet suggests that they preferentially feed on caribou and muskoxen, but can sustain themselves on arctic hares and northern collared lemmings in areas with limited or no ungulate populations.

Brown bear and Polar bear

Until recently, the range of the brown bear, or grizzly ([Fig. 4](#)), extended north to the Arctic Sea coasts of North America and Eurasia. As their populations approach their northern limits, the home ranges of brown bears increase in size. A study by [Edwards et al. \(2009\)](#) found that male bear home ranges in the Mackenzie Delta region of northwest Canada averaged just over 1200 km² while female home ranges were about 680 km². By way of comparison, the home ranges of brown bears on the Japanese island of Hokkaido are about 28–50 km². Since about 2000, brown bears have begun appearing on the High Arctic Islands of northwest Canada. The first documented sighting of brown bears in this region came during geological fieldwork Melville Island in 2003–2004. DNA from a hair sample collected here matches brown bear populations along the northern mainland coast.

Because of their low population density in the Arctic, brown bears must also roam great distances to find mates. However, a study of mating behavior by [Edwards and Derocher \(2015\)](#) found that brown bears near the northern edge of the species' range in the Canadian Arctic devote more time and energy seeking out food, than seeking mates. Finding quality habitat with better food resources appears to take precedence over finding a mate. The recent northward advance of brown bears onto the Canadian Arctic Archipelago has brought this species into more regular contact with polar bears, with some interesting consequences. Over the last decade, brown bears have been mating with polar bears in this region. Using genetic evidence, [Pongracz et al. \(2017\)](#) were able to trace eight hybrid individuals to a single female polar bear who mated with two grizzly bears in recent years.

The polar bear's scientific name is *Ursus maritimus*—the marine bear ([Fig. 8](#)). This is a very good name for a bear that spends the majority of the year at sea, hunting from the pack ice. Their coats are pure white, year-round. This provides good camouflage when hunting on the ice, as the only parts of the bear that are not white are the eyes and the nose (they have been seen covering their black noses with their paws when stalking seals). This bear ranges across the whole High Arctic region, coming ashore in northern Canada, Greenland, Svalbard, northern Scandinavia, northern Siberia, and northern Alaska. These bears are solitary for most of the year, seeking each other out only during the mating season (March through May). Pregnant females find dens in late October through November; their dens may be on land near the coast, or on the pack ice. Pregnant polar bears that enter maternity dens in late summer/autumn may fast for up to 8 months in addition to meeting the nutritional demands of gestation and lactation. Prior to entering dens, pregnant females are obese, containing as much as one pound of fat per pound of lean body mass. While fasting, bears lose about 43% of their body mass. Of the total energy expended on maintenance and reproduction, >90% is drawn from fat stores. Fatter bears produce heavier cubs that are more likely to survive. The young are born in December, and the mother and cubs emerge from their den in late March or early April. The cubs remain with their mother for about 2 years, and females generally breed every 3 years.

Polar bears are the only truly carnivorous bears in the Arctic. Their diet consists almost entirely of meat. They are also very large, with adult males averaging 273–545 kg and females averaging 182–318 kg. The largest recorded male weighed 726 kg. The life span of the polar bear is about 25 years, but only a small proportion of polar bears live past 15–18 years.

These bears are highly mobile, as revealed by research using satellite telemetry. The movements of an adult female polar bear were monitored as she traveled from the Alaskan Beaufort Sea coast to northern Greenland. Polar bears are very proficient at hunting seals from pack ice. They are the most important predator of ringed seal. A study from the Canadian High Arctic showed that 10–24% of hunting attempts were successful, with seal pups making up 75–100% of the seals killed. Polar bears are also known attack beluga whales. Bear predation may occur when whales are entrapped by ice or while whales are passing through leads or surfacing at holes in melting ice sheets. While this predation has little effect on beluga populations, belugas are large in comparison to other polar bear prey, and may be of some local importance in polar bear diets.

Polar bears have some remarkable adaptations for life in arctic seas. Their fur appears white, but individual hairs have almost no pigment, and are hollow. These clear, hollow hairs act as tiny greenhouses to trap light and hold its warmth next to the bear's skin. Since they spend much of their time in sea water that is very near the freezing point, these bears must be well-insulated to protect against hypothermia. Their layer of blubber is up to 11 cm thick beneath the skin, and forms excellent insulation from cold water. These bears need lots of high-energy food to sustain themselves, and they consume an average of 2 kg of fat per day. A ringed seal weighing 55 kg provides enough fat to sustain a bear for up to 8 days. Polar bears digest fat more efficiently than protein.

Polar bears are currently listed as "Vulnerable" by the International Union for the Conservation of Nature (IUCN), principally because of the current and predicted future loss of critical sea-ice habitat. The IUCN predicts a decline of >30% of the polar bear population size in the coming decades. However, that projection was based on the IPCC report of 2013, which was more conservative in its sea-ice loss estimates. [Hoegh-Guldberg et al. \(2018\)](#), in the most recent IPCC report, now estimate that just a 1.5–2°C

Fig. 8 A polar bear tests the strength of thin sea ice. Photo by Mario Hoppmann, NASA.

warming above historical temperature levels will increase the risk of an ice free Arctic Ocean to 50% or higher. This loss of sea ice would mean a critical loss of habitat for polar bears. They would no longer have any effective means of hunting for seals, their primary prey.

As if habitat loss were not sufficiently threatening to polar bear survival, these top-end marine predators are also being systematically poisoned by industrial chemicals that pass up the food chain from marine plankton to fish, from fish to seals, and from seals to polar bears.

The suite of toxic chemical substances found in arctic waters includes persistent organic pollutants (POPs) such as polychlorinated biphenyls (PCBs) as well as the more recently developed POPs such as brominated flame retardants and other toxic compounds. These chemicals, and heavy metals such as mercury, tend to accumulate in the tissues of vertebrates. Because the polar seas are now contaminated by these pollutants, arctic marine life has been poisoned by them. These pollutants accumulate in the fatty tissues of marine mammals, so their concentrations become far higher than those found in organisms lower down the food chain. A summary of the accumulation of organic pollutants and mercury in Canadian arctic vertebrates by Braune et al. (2005) showed that the concentrations of PCBs in zooplankton range from about 15–55 nanograms per gram of dry weight. By the time these pollutants have passed up the food chain to polar bears, their concentration in polar bear fat is about 1000–2500 nanograms per gram of fat, or up to 166 times higher than it is at the bottom of the marine food chain.

A detailed, long-term assessment of the impacts of POPs on Greenland polar bear health was published by Dietz et al. (2018). They found that the risk quotients from exposure to POPs have been above the toxic threshold for the reproductive and immune systems of polar bears throughout all 30 years of testing (1983–2013). The risks of various cancers were also above the toxic threshold for this period.

Conclusions

The terrestrial vertebrate fauna of the High Arctic consists of just a few species of mammals that are highly adapted to the rigors of life in this highly inhospitable region. The active season is very short and food resources are extremely limited, yet these animals have adapted to these conditions, and also manage to survive the incredibly long, cold winter season. Year-to-year survival in the High Arctic is often precarious. Seemingly small changes in the environment may tip the balance for these animals. That is why the current anthropogenic changes to arctic environments are so potentially hazardous to regional ecosystems. A simplistic view might be that global warming will be of great benefit to High Arctic ecosystems, reducing the harshness of the climate and thereby making survival of the flora and fauna easier. Unfortunately this is not the case. The high arctic biota has evolved adaptations for cold climate—not warm. The muskoxen and caribou graze on the kind of herbaceous tundra vegetation that grows in a cold, dry Arctic climate. As the climate warms, this vegetation gives way to shrubby vegetation that is far less suitable for grazers. The polar bear needs pack ice cover from which to hunt seals in the Arctic Ocean. The disappearance of pack ice may open up Arctic shipping lanes for boats, but it also would eliminate critical habitat for polar bears. Persistent organic pollutants (POPs) may not have been manufactured in the Arctic, but they now reach all oceans waters of the world, even at the highest latitudes.

As the world warms, the Arctic regions warm with greater amplitude, so that a 1.5°C average global warming will likely bring warming of up to 8°C to the Arctic. During the Middle Pliocene Warm Period, the most recent time period when CO₂ concentrations were similar to present, the global temperature was > 1°C and Arctic temperatures about 8°C warmer than preindustrial levels (Brigham-Grette et al., 2013). Unfortunately, the very adaptations that fit mammals for life in the High Arctic may prove to be their downfall as their homelands become essentially uninhabitable to them.

Abstract

This article deals with the marine plankton of the High Arctic region, which includes both highly productive shelf regions and polynyas, and extremely oligotrophic basins above 70° latitude. Living phytoplankton and associated heterotrophic single celled microbial eukaryotes, Bacteria, Archaea and viruses are suspended in the water column. Zooplankton are also displaced by currents, but are often vertically mobile and migrate up and down the water column. The plankton form complex trophic webs that support substantial populations of marine mammals and birds. Phytoplankton and other microbial eukaryotes are the primary food for crustacean copepods that account for much of the plankton biomass in the Arctic Ocean. Microbial plankton are also food for gelatinous zooplankton, which can occasionally form blooms in the high Arctic. The upper waters of the Arctic are relatively less saline than deeper waters, creating a stratified water column separating the photic zone from the nutrient rich deep waters. The lack of light for much of the year combined with ice cover, constrains annual photosynthetic productivity by the phytoplankton. Under a warming climate, early ice melt and increasing open waters could increase net production, however ice-melt also adds fresher less dense water to the surface leading to greater stratification, preventing nutrients from entering the photic zone. This means that although some marginal seas of the Arctic may see increased production, the high Arctic could actually become more oligotrophic and unable support displaced populations of marine mammals that rely on ice during much of their life cycles.

Introduction

The Arctic Ocean is surrounded by land with inputs of Atlantic-origin water through Fram Strait and the Barents Sea, Pacific-origin water through Bering Strait to the Chukchi Sea shelf and large freshwater inputs from the surrounding continents of Eurasia and North America. Upon entering the Arctic, the Pacific and Atlantic water masses move below the surface mixed layer and flow across relatively shallow (200 m) shelves before entering the two main Arctic basins, which are separated by undersea ridges. Water is constrained and circulates within the basins, and the timing and extent of waters flowing out of the central Arctic is strongly linked to the Atmospheric Oscillations in the Arctic and North Atlantic (Proshutinsky et al., 2015). Within the Arctic Ocean, waters are

substantially modified by physical and biogeochemical processes prior to flowing into the North Atlantic via several routes: Fram Strait east of Greenland, the complex straits and channels of the Canadian Arctic Archipelago and Nares Strait, which is between Greenland and Ellesmere Island Canada (Williams and Carmack, 2015).

Light and nutrient availability generally limit production in the Arctic Ocean, with multiyear ice persisting in higher latitudes, while other regions are covered with seasonal ice well into June or July. The complex currents and circulation in the Arctic Ocean result in major differences in overall productivity among Arctic regions. The most productive areas in the High Arctic are across the inflow shelves and in polynyas, which are open waters surrounded by ice. Most Arctic polynyas occur where wind and latent heat maintain ice free conditions, or by tidal forcing within smaller inlets. For these polynyas, the early access to light and resuspension of nutrients prolongs the normally short arctic phytoplankton bloom (Booth et al., 2002), which helps maintain diverse zooplankton communities (Dvoretzky and Dvoretzky, 2015).

Until recently, the productivity of the deep basins has been primarily limited by light, which is blocked by thick multiyear ice preventing photosynthesis in summer. This is changing because the Arctic is warming more rapidly than global averages and much of the multi-year ice is becoming seasonal (Bluhm et al., 2015). However, higher productivity may not necessarily follow, as nutrients can remain trapped below the upper mixed layer and out of the euphotic zone (Hunt et al., 2016). Given the few connections between the Arctic and the World Ocean, it is not surprising that, just as many marine mammals are endemic and confined to the Arctic, so too are many of the planktonic species that support them.

Plankton refers to taxonomically and functionally diverse aquatic organisms that passively move with ocean currents. Plankton range in size from submicron ($<0.1\ \mu\text{m}$) to decimeters or even meters in the case of jellyfish and other colonial zooplankton (Purcell et al., 2010). Plankton historically were classified into the functionally defined categories of phytoplankton and zooplankton, a bifurcation that followed an Aristotelian view of the natural world consisting of plants and animals. The analogy with plants was logical since phytoplankton have chloroplasts and carry out photosynthesis and zooplankton are animals visible to the naked eye and at the base of a food chain leading to the larger animals that are harvested from the sea for food and material goods.

As tools for examining biodiversity have expanded, first by way of high-resolution microscopy, and more recently using molecular techniques, it is clear that plankton in the Arctic and elsewhere are much more diverse than previously imagined. This holds true for both the visible zooplankton, where species and populations are more easily distinguished using DNA markers (Choquet et al., 2017) and more profoundly among the microscopic, mostly single celled plankton that include three domains of life: Eukaryota, Bacteria and Archaea (Pedros-Alio et al., 2015), and the viruses that infect them (Gregory et al., 2019). The plummeting cost of DNA sequencing has resulted in a proliferation of environmental gene surveys that are able to distinguish the staggering range of evolutionarily distinct lineages within microscopic plankton. The small subunit ribosomal RNA gene (SS rRNA) is particularly useful since it is universal and has both conserved regions amiable to primer design and variable regions that can be used as genetic markers. The 16S rRNA gene for Bacteria and Archaea and the 18S rRNA gene for Eukaryota are suitable for reconstructing evolutionary relatedness (phylogeny) and identifying organisms, often to the level of species. One result of the now widespread use of SS rRNA gene surveys is the realization that microscopic plankton form complex ecological systems, rather than linear food chains. The interactions among microbial plankton maintain global ecosystem services, such as carrying out key steps in carbon, nitrogen and sulfur cycles and producing about half of the oxygen in the atmosphere. Of relevance here is that microscopic plankton maintain the biodiversity of animals in both pelagic and benthic habitats in the Arctic, and more generally in the Global Ocean. Here I provide a brief introduction to the planktonic zooplankton in the Arctic, followed by more detailed descriptions of the newly appreciated diversity of the microbial eukaryotic plankton, with a brief summary the co-occurring Bacteria and Archaea.

Metazoan Zooplankton

Metazoan zooplankton are true animals and, in the Arctic Ocean, as elsewhere, include an array of invertebrates, including some invertebrate larval stages as well as larval stages of fish (ichthyoplankton). However, here we focus on zooplankton that are planktonic for their entire life cycle. The majority of zooplankton actively swim and have some control over their vertical position in the water column. Copepods in particular carry out daily and seasonal vertical migrations (Darnis et al., 2017). Newly hatched invertebrate zooplankton live for months to years and most have well defined life cycles, with feeding and egg production closely tied to ice algal and phytoplankton productivity (Leu et al., 2011; Dvoretzky and Dvoretzky, 2015), with predictable seasonal cycles. Most deep water species are also found within specific depth ranges across the Arctic's central basins (Kosobokova and Hopcroft, 2010).

Arctic zooplankton are taxonomically and trophically diverse, ranging from species that consume bacteria and single celled microbial eukaryotes to those that prey on other zooplankton. Around one-quarter of the zooplankton species found in the Arctic are restricted to the Arctic, with most other species shared with the plankton fauna of the North Atlantic or North Pacific (Lovejoy et al., 2017). By far the best-studied zooplankton in the Arctic are copepods. These are estimated to account for 80–90% of the zooplankton biomass in the Arctic, with over 150 copepod species among the c. 350 zooplankton species reported for Arctic (Bluhm et al., 2011).

Copepods are directly consumed by many fish, some seabirds, and baleen whales (Darnis et al., 2012). Three species of *Calanus*, with somewhat similar life cycles, dominate Arctic zooplankton; *C. glacialis*, *C. hyperboreus*, *C. finmarchicus*. All three species feed in surface waters during spring and summer with daily migrations in and out of the photic zone. They migrate to deeper waters over winter, triggered by day-length or in response to “adequate” lipid stores (Hafker et al., 2018; Schmid et al., 2018). Once in the deep

waters they maintain low metabolic rates referred to as diapause until spring, when they return to the surface in response to physiological or environmental signals.

Larger crustaceans such as hyperiid amphipods and euphausiids (krill) feed on smaller zooplankton and in turn serve as prey for marine vertebrates. Arctic euphausiids are mostly reported at the inflows to the Arctic and in more productive regions, but are almost absent from the central basins (Lovejoy et al., 2017). The most widespread free-living hyperiid amphipods are species of *Themisto*.

Another ubiquitous zooplankton group in the Arctic Ocean and surrounding seas are the appendicularian tunicates *Oikopleura vanhoeffeni* and *Fritillaria borealis*, which are widespread in productive open water regions of the Arctic (Deibel et al., 2017). Appendicularia are suspension feeders, making a mucilaginous “house” that collects bacteria and small phytoplankton. The “house” and trapped prey are subsequently consumed by the animals, creating a key linkage between the smallest microbial plankton and higher trophic levels.

Microbial Plankton

Phytoplankton are colored and as in higher plants, the primary pigment used for photosynthesis is Chlorophyll *a* (Chl *a*). Other pigments such as beta carotenoids and mycosporine-like amino acids are photoprotective and absorb harmful UV radiation. Phytoplankton species range in size from 1 µm to over 200 µm and while many are single celled others are colonial, and can occur as ribbons of cells, spheres or beautifully arranged branching colonies. While by definition all phytoplankton are photosynthetic, many species can also capture bacteria and other small cells for energy and nutrients, making them mixotrophic. Other microbial eukaryotes are heterotrophic and include bacterial grazers that adhere to particles and consume attached bacteria, and predators that capture bacteria or other eukaryotes using a variety of techniques. With few exceptions the microbial eukaryotes are food for macroscopic zooplankton.

Under natural light, the Chl *a* molecule is green, but other cellular pigments and cell structures often mask the presence of chlorophyll in both live and preserved samples. A useful characteristic of Chl *a* is that it fluoresces red when excited by blue wavelengths of light, which makes it simple to visualize even tiny chloroplast-containing cells using epifluorescence microscopy (Fig. 1). With rare exceptions, arctic phytoplankton are microbial eukaryotes with membrane-bound chloroplasts. These microbial eukaryotes are evolutionarily diverse with lineage-specific ancillary pigments that can be used to characterize bulk communities in the Arctic (Vidussi et al., 2004). Aside from Chl *a*, the major pigments used to capture photons include chlorophylls *b* and *c*₁, *c*₂ and *c*₃ and several other specific pigments including fucoxanthin (Fuco) and prasinoxanthin (Pras).

Established classification systems following botanical and zoological nomenclature rules do not accurately reflect our current understanding of the evolutionary histories of microbial eukaryotes. Higher order taxonomic relationships are in flux, and as more genomes become available, emerging phylogenies are only partially reconciled with established taxonomies. More detail on recent higher order classifications can be found in (Adl et al., 2019). Adl et al. (2019) also attempted to standardize functional terminology and I follow their suggestions here, with the exception that I use the more common term flagella, rather cilium, for cellular structures that are primarily involved in physical displacement of free living cells. The approach here is to discuss the more common groups of phytoplankton and single celled heterotrophs, and to mention ecological interactions with viruses, bacteria and zooplankton, where known.

Chlorophyta

Chlorophyta or “green algae” are green due to the presence of an additional chlorophyll pigment, chlorophyll *b*, which is also found in land plants. They are taxonomically diverse with a dozen or so major evolutionary lines, many of which are found only in freshwaters. The chlorophytes in Arctic phytoplankton are mostly confined to three major lineages; Chlorophyceae, Mamiellophyceae (Mamiellales) and Pyramimonadales. The Chlorophyceae in the Arctic mostly occur in sea ice and melt ponds (Poulin et al., 2011) and are rare in the plankton, but several *Chlamydomonas* species may occur in the plankton associated with sea ice melt. The Mamiellales are mostly smaller than 5 µm with three picoplankton (<2 µm) size genera; *Micromonas* (Fig. 1), *Bathycoccus*, and *Ostreococcus*, with *Ostreococcus* restricted to warmer regions and not found in the Arctic. Molecular analysis has recently revealed that the genus *Micromonas* contains multiple species including one likely Arctic endemic species *M. polaris* (Simon et al., 2017), which dominates the pico-sized phytoplankton in most Arctic marine waters (Lovejoy et al., 2007). Other *Micromonas* spp. and *Bathycoccus prasinos* are also recovered in molecular gene surveys, usually at lower proportions compared to *M. polaris*. These may reflect seasonal differences or complex host-viral interactions (Joli et al., 2017). The two genera differ, despite their similarly tiny size, in both morphology and behavior, with the *Micromonas* being motile with one short flagellum and *Bathycoccus* having scales that may serve a defensive role. One other genus in the Mamiellales, *Mantoniella*, is slightly larger and occasionally reported. The third green algal group, Pyramimonadales are often reported from microscopy, in marker gene surveys and from culturing studies, with *Pyramimonas* the most common genus. *Pyramimonas* species tend to be bright green and with 4 flagella but can have up to 8. A number of species are likely to be restricted to the Arctic (Daugbjerg and Moestrup, 1993; Balzano et al., 2012; Haroardottir et al., 2014). This genus has also been associated with ice and ice to open water transitions (Haroardottir et al., 2014).

Cryptophyceae

Cryptophytes have two unequal flagella that move independently in the forward and reverse directions, enabling them to swim short distances. Many cryptophytes are easily recognized by general morphology with droplet-shaped cells, the two flagella and furrow-gullet complex referred to as an oral groove. Cryptophytes are also mixotrophic and capture small prey items, such as bacteria. This provides considerable metabolic flexibility, enabling the cells to function in both photosynthetic autotrophic and heterotrophic modes. The photosynthetic cryptophytes contain chlorophylls *a* and *c*₂, xanthophylls and blue-green or red phyco-biliproteins that fluoresce bright red or orange under epifluorescence microscopy. At least one endemic species *Baffinella frigidus* has been isolated from the Arctic, and tolerates a range of light and salinity conditions but not temperatures above 9 or 10 °C (Daugbjerg et al., 2018). Other genera such as *Teleaulax* and *Rhodomonas* have been reported from microscopy but molecular gene surveys suggest that these may also be divergent and represent new species (Lovejoy et al., 2006). One cryptophyte genus reported in the Arctic is *Goniomonas* (Poulin et al., 2011). This genus lacks functional chloroplasts and requires bacterial prey. In addition, distantly related to the cryptophytes, are the kathablepharids, which are also colorless predators targeting bacteria, and are occasionally reported both from microscopy and 18S rRNA gene surveys in the Arctic.

Stramenopiles—Heterokonts

Stramenopiles include lineages that have, or ancestrally had, two structurally different flagella at some stage in their life cycle. The term heterokont refers to the flagella, one smooth and the other called a flimmer flagellum because it is covered in the small hair-like structures called tripartite mastigonemes. The higher-level botanical classification Heterokonta was applied to brown and golden algae and has been largely replaced by the more inclusive term Stramenopiles. This major branch of eukaryotes includes single cells ranging from 1 µm diameter to giant kelp. While many are photosynthetic, there are also parasitic and heterotrophic representatives that do not have functional chloroplasts. The planktonic lineages detailed below are ubiquitous with pan-arctic distributions.

Chrysophyceae

Chrysophytes contain chlorophyll *a*, chlorophyll *c*, and are often called golden algae because of the presence of fucoxanthin, a yellowish-brown carotenoid pigment. Currently five Order level lineages are recognized with four of these being found mostly in freshwaters. Most marine chrysophytes are in the order Ochromonadales, with several species common in the arctic phytoplankton. Many chrysophytes are unicellular and free swimming, but others such as *Dinobryon* live in vase-shaped loricae, made of chitin fibrils and polysaccharides. Several species of solitary *Dinobryon* have been reported from the Arctic, but the most common and sometimes very abundant species is *D. balticum* which forms large colonies, with the lorica arranged in a way that resemble branching trees, and a with a single cell within each lorica (Fig. 2). *Dinobryon*, as well as single celled ochromonads, are mixotrophic. Several single celled Arctic ochromonads have been isolated and maintained in culture, including one undescribed species (CCMP2298) that requires bacteria or high concentrations of organic matter for growth, since it cannot take up inorganic nitrogen (Terrado et al., 2015). Another common ochromonad genus in the Arctic, *Spumella* is colorless (Balzano et al., 2012) and requires bacteria or organic matter for both carbon and nitrogen.

Pelagophyceae

Pelagophytes are small usually coccoid cells, with one or two flagella usually present (Fig. 2). They are distantly related to the chrysophytes with ancillary chlorophylls c1 and c2. They first came to the attention of phycologists when they were identified as sources of harmful algal blooms forming “brown tides”. To date, brown-tide forming species of pelagophytes have not been conclusively found in the Arctic, but several diverse undescribed pelagophytes have been recovered in molecular surveys (Lovejoy et al., 2006; Marquardt et al., 2016) and have cultured representatives (Terrado et al., 2015; Balzano et al., 2012). Pelagophyte blooms appear to be linked to coastal hydrological changes and nutrient enrichment, and should be monitored in the Arctic.

Dictyochophyceae

There are two recognized orders of Dictyochophyceae found in the Arctic Ocean: Dictyochaetales with silica skeletons present for at least part of their life cycle and Pedinellales. The Dictyochaetales have been reported from the Arctic for over 100 years and are easily recognized by their distinct skeletons, using light microscopy (Lovejoy et al., 2002a,b). The second order consists of both chloroplast-containing and aplastidic genera, that tend to attach to particles and capture passing bacteria. The chloroplast-containing Dictyochophyceae are mixotrophic and also prey on bacteria. At least one Pedinellales is recorded from gene surveys, has cultured representatives and is likely endemic (Terrado et al., 2015).

Bolidophyceae–Parmales

These small cells are phylogenetically related to diatoms. They occur as either rapidly swimming cells (bolidophytes) or non-motile cells covered in silica plates (parmales). The ridges of the plates can be quite decorative. The morphologically distinct parmales were first identified using scanning electron microscopy on samples from cold waters, whereas the bolidophytes were isolated and then characterized genetically. It was only later that it was realized that they were related and it has been suggested that they represent different life stages (Ichinomiya et al., 2011). Bolidophytes and Parmales are ubiquitous in Arctic plankton but are rarely found at high relative concentrations.

Diatoms

In the Arctic diatoms occur as either solitary or joined, often resembling chains and ribbons (Fig. 2), and are both planktonic, and a major component of the ice algae. Diatom cells range from 2 µm to over 200 µm in diameter. Because they rely on silicon for cell wall formation, growth and reproduction of diatoms is often limited by silicon supply. Diatoms have complex life cycles, where cells typically become smaller with multiple divisions due to the constraints of their silica cell wall, and after an extended pelagic growth phase form larger cells usually following sexual recombination (D'Alelio et al., 2010).

Diatoms are among the most abundant, widespread and productive phytoplankton in Arctic waters, and serve a central role in planktonic food webs. Recently re-examination of the morphological details and the availability of molecular phylogenies have upended the traditional Centric versus Pennate diatom dogma. Today, generally three major lineages are recognized, however with more molecular data becoming available from more taxa this may change. What were previously called centric diatoms are now divided into two major lineages corresponding to the Classes Mediophyceae and Coscinodiscophyceae, with the pennate Bacillariophyceae remaining as a third Class. The Coscinodiscophyceae encompasses radially centric groups that look like round pill boxes. In the Arctic these round diatoms include large *Coscinodiscus* species that occur early in the spring bloom (Lovejoy et al., 2002a,b) and are an important source of nutrition for the largest arctic copepod *Calanus glacialis*. The second lineage, Mediophyceae can appear to be quite round, for example *Thalassiosira* spp., but have two or more poles of centricity. Mediophyceae includes many of the iconic late spring and summer diatoms including two arctic species of *Chaetoceros*, *C. gelidus* (Chamnansinp et al., 2013), and *C. neogracilis* (Balzano et al., 2017), and *Thalassiosira* species that form necklace like strings of cells in late spring. *Thalassiosira antarctica* var. *borealis* and several other species may be restricted to the Arctic and often co-occur with more boreal species (Luddington et al., 2016).

The pennate Bacillariophyceae are much more common in the ice where they live in brine channels and are released to the water column when sea ice melts in spring. These ice algae sink rapidly out of the photic zone but are occasionally recovered in plankton nets. During the spring bloom ribbon chains of several species of diatoms can also dominate biomass (Fig. 5) Later in the season the planktonic pennate genus, *Pseudo-nitzschia*, can release a toxin that causes amnesia in vertebrates (D'Agostino et al., 2017). For instance, marine mammals become disoriented and forget to feed their young. *Pseudo-nitzschia* species are consistently reported from the Arctic but usually at low concentrations and at least one species *P. arctica* may be endemic (Percopo et al., 2016). The causes of toxin producing *Pseudo-nitzschia* blooms are unclear, but may be related to overall nutrient ratios, and the availability micronutrients such as iron. In the Baffin Bay region, *Pseudo-nitzschia* could be favored by the input of micronutrients from the melting of the Greenland Ice Sheet (Joli et al., 2018). In essence there is a real danger of blooms becoming more common and releasing toxins (Harardottir et al., 2015) and potential harm to marine mammals should not be ignored.

Marine Stramenopiles (MASTs)

The MASTs consist of clades of Stramenopiles that are mostly uncultivated and known from 18S rRNA gene surveys. Seven MAST clades are reported from the Arctic (MASTs 1a, 1b, 1c, 2, 3, 7 and 8) and tend to occur in upper waters (Monier et al., 2013), where the higher productivity by the photosynthetic groups supports bacterial prey for these small heterotrophs.

Haptophyta

The most conspicuous, well-known haptophytes, are coccolithophorids that are covered in calcium carbonate “coccoliths,” which are the source of ancient deposits of calcareous earth. Arguably the most successful haptophyte on Earth is *Emiliania huxleyi*, which forms vast blooms in the North Atlantic and elsewhere. However, to date, no blooms have been reported from the Arctic, and coccolithophorids tend to be absent from High Arctic molecular gene surveys. Non-coccolithoid haptophytes fall into two major clades: the Prymnesiophyceae and the Pavlovaales. Both lineages are primarily unicellular, with chlorophylls a and c, and are often a golden-brown color because of the presence of the carotenoid accessory pigments diadinoxanthin and fucoxanthin. The motile

Prymnesiophyceae usually have two equal flagella and a haptonema, which is a filamentous appendage that is used for capturing bacteria and small phytoplankton prey.

Two genera of Prymnesiophyceae are frequently reported from the Arctic: *Chrysochromulina* and *Phaeocystis*. Several *Chrysochromulina* species are able to produce ichthyotoxins, which can harm or kill fish, but to date no such events have been documented in the Arctic. Both genera produce dimethyl sulfide (DMS), which can form cloud nuclei when released to the atmosphere, but is usually rapidly scavenged by marine bacteria as a source of organic carbon and sulfur (Motard-Cote et al., 2012). At low concentrations DMS is associated with the “smell of the sea” but at high concentrations is noxious-smelling and can alter fish migration routes. *Phaeocystis pouchetii* can occur as either small motile single cells or form larger gelatinous colonies composed of non-motile cells. In less oligotrophic Arctic regions *Phaeocystis pouchetii* proliferates toward the end of the spring diatom bloom, when silicon concentrations tend to limit diatom growth. This species seems to be quite flexible and persists over the polar night (Vader et al., 2015) and has also been implicated in under-ice blooms (Kauko et al., 2019). In contrast to the Prymnesiophyceae, Pavlovales are rare. The small solitary cells have one or two visible flagella and a rudimentary haptonema. A cultured representative referred to as CCMP2436 in Terrado et al. (2015) although not yet described, is likely endemic (Fig. 3).

Alveolates

Dinoflagellates and ciliates form a monophyletic super group referred to as Alveolates. Ciliates and dinoflagellates tend to have larger cells and contain large genomes and multiple copies of rRNA genes, which means that they tend to be over-represented in gene marker surveys. Apart from spring diatom blooms, these large cells also dominate net plankton (>50 µm). Because they tend to capture and eat phytoplankton, they are often referred to as microzooplankton. The efficacy of microzooplankton grazing in the Arctic varies (Sherr et al., 2009).

Dinoflagellata

Dinophyceae, referred to as core dinoflagellates, range from less than 10 µm to over 1000 µm and although often occurring as single cells, many species can also form long swimming chains. The core dinoflagellates usually have two flagella, with one transverse and the other longitudinal. In combination, this results in rapid forward and lateral movement (Video 1 in the online version at <https://doi.org/10.1016/B978-0-12-409548-9.11979-7>). Dinoflagellates are surrounded by a complex covering called the amphiesma, which consists of outer and inner continuous membranes, and between which lie a series of flattened vesicles. In armored forms, these vesicles contain cellulose plates called thecae. The surface plate patterns of theca are used to classify dinoflagellates. If this armor is lacking or shed under certain environmental conditions, the cells are called athecate. Even for athecate species, patterns similar to plate patterns can be discerned using transmission electron microscopy, these are used in their taxonomic classification. Under epifluorescence microscopy dinoflagellates tend to be easy to recognize when stained using a nucleic acid fluorochromes as the nucleus appears to be granular since their chromosomes lack histones and are not condensed (Fig. 4A).

Around half of described dinoflagellates are photosynthetic, possessing chlorophyll *a*, other chlorophylls and often the carotenoid peridinin. Non-peridinin dinoflagellates seem to be particularly common in the Arctic (Onda et al., 2017). Among these are dinoflagellates, which have acquired chloroplasts from other algae, including prasinophytes, haptophytes, cryptophytes

Fig. 3 (A) Two cells from a culture (CCMP2436) of a Pavlova (Haptophyta) from Northern Baffin Bay. False color composite of a confocal laser microscopy image, showing the position of the chloroplasts in the cell. Note the unequal flagella in this species, the vestigial haptonema is not visible in the light micrograph. (B) Scanning Electron Microscope image of a cell from the same culture after critical point drying to see surface features, kindly provided by Dr. Wenche Eikrem at the Department of Biosciences, University of Oslo.

This cell is c. 20 μm long; (B) Oligotrichous ciliate, *Laboea strobila*, green color is from chloroplasts captured from prey; (C) Tintinnid ciliate *Ptychocylis obtusa*. The black scale bar (B and C) is 25 μm .

and even diatoms (Janouskovec et al., 2017). Most photosynthetic dinoflagellates are facultative heterotrophs, engulfing and ingesting bacteria and phytoplankton as prey. Dinoflagellates can form large, and in some cases harmful, blooms but to date none have been reported in the Arctic. However, microscopy and 18S rRNA gene surveys have revealed the presence of potentially harmful genera including *Gyrodinium*, *Dinophysis* and *Prorocentrum* (Poulin et al., 2011; Onda et al., 2017).

Approximately 50% of dinoflagellates lack functional chloroplasts and need to feed on other microscopic plankton. The larger thecate forms tend to prey on other phytoplankton and ciliates using an incredible array of attack and ingestion methods, for example some single celled dinoflagellates can consume entire chains of diatoms (Jacobson and Anderson, 1986). Several dinoflagellates produce light through bioluminescence, which can be seen during the Polar night (Cronin et al., 2016). Dinoflagellates also have complex life cycles with both asexual and sexual stages forming cysts (Video 1 in the online version at <https://doi.org/10.1016/B978-0-12-409548-9.11979-7>) that are able to survive in the sediment over long periods of time. For many of these cysts the vegetative form of the cell is unknown and paleo-oceanographers have devised a separate cyst-based taxonomy based on cyst morphology to reconstruct past climates (de Vernal et al., 2013). However, many of these dinoflagellates are not ancient extinct

forms and accurate interpretation of climate proxies would benefit by matching living dinoflagellates with their cysts (Potvin et al., 2013). This also highlights the more general problem that a high proportion of dinoflagellates from Arctic samples cannot be identified to species from their 18S rRNA. An additional marker gene, such as the Large Subunit of the rRNA gene, seems to be needed to separate dinoflagellate species. Most smaller athecate species, which are particularly common in the Arctic (Onda et al., 2017), (Fig. 4A) have not been morphologically described, and there are few reports matching morphological and genetic data. In parallel, there are many morphological species of dinoflagellates that have been validly described, but have only been reported once (Thessen et al., 2012), increasing the difficulty of reconciling gene markers with morpho-species.

Distinct from the core dinoflagellates are Syndinales. Known species are parasites on zooplankton, fish and other protists. The Euduboscquellidae, which target ciliates and Radiolaria and the poorly known Ellobiopsidae that parasitize copepods, are almost always recovered in Arctic gene surveys along with Amoeboophryidae that target core dinoflagellates (Onda et al., 2017). The majority of the Syndinales are known only from gene surveys and are referred to as different clades of Marine Alveolates or MALVs. These seem to be particularly common in the Arctic and can dominate 18S rRNA gene surveys.

Ciliates

Ciliates, like dinoflagellates, tend to be larger and the literature on morphological species for the most part has not been paired with molecular surveys. In particular, tintinnid ciliates are characterized by their loricas (Fig. 4C) and some species appear to be widespread in the Arctic (Dolan et al., 2017). This is in contrast to molecular marker studies in which many ciliates can only be identified to the order level of order or higher, because of a lack of reference sequences. As with dinoflagellates, there is a need to closely examine the validity of species that are only known from their original morphological descriptions. One advantage of gene surveys is that it is evident that certain ribotypes are widespread in the Arctic, with pan-arctic distributions (Onda et al., 2017; Lovejoy et al., 2006; Marquardt et al., 2016). Many ciliates in the Arctic also appear to be kleptoplastidic, meaning that they acquire and maintain the chloroplasts of specific co-occurring algae over long periods of time. These include the common coastal species complex *Mesodinium rubrum* and *Laboea strobila* (Fig. 4B).

Other Heterotrophic Groups

Heterotrophic groups with diverse prey preferences and feeding strategies need to be considered in the wider context of how the planktonic biome of the Arctic Ocean functions. A brief summary of the most frequently encountered groups follows.

Rhizaria

Rhizaria are a supergroup of diverse lineages of microbial eukaryotes that have pseudopodia used for feeding and movement. They range from small (5–15 µm) flagellates to >500 µm cells with mineral skeletons or spines. Among the smaller Rhizaria are the Cryomonadida, represented by the pan-arctic genus *Cryothecomonas*, (Fig. 5B), which is associated with ice edge blooms and likely parasitizes diatoms (Thaler and Lovejoy, 2012). Other Rhizaria were first collected in the 19th century and described by Haeckel (Caron, 2016). Most of the major lineages have been reported from the Arctic. These include Phaeodrea, Acantharea, Taxopodida, and Polycystinea (Lovejoy et al., 2006; Monier et al., 2013; Dolan et al., 2014; Ikenoue et al., 2019). Many of these species evidently form complex symbiotic relationships with other organisms and further ecological work in the Arctic is needed.

Choanoflagellata

Choanoflagellates are small cells (5–20 µm) with a single flagellum that is surrounded by a distinct “collar,” used to capture and ingest bacterial prey (Fig. 5A). The choanoflagellates are distantly related to animals and fungi. The majority of choanoflagellates

Fig. 5 Other heterotrophic flagellates. (A) collared choanoflagellate under blue excitation. The bright green autofluorescence is common among heterotrophic groups; (B) *Cryothecomonas* sp.; (C) *Telonema* sp. All cells are c. 10 µm.

reported from the Arctic are in the Acanthoecida, with taxonomically characteristic lorica made up of silica containing costal strips. Many morphologically undifferentiated Acanthoecida are persistently reported from 18S rRNA gene surveys, but the most complete study to date relied mostly on microscopy, with 50 or so taxa reported, including likely endemic species (Thomsen and Ostergaard, 2017).

Microbial fungi

Although Fungi were once classified with plants, they are a sister clade to multicellular animals. Marine fungi tend to be microscopic and do not form the large reproductive structures typical of many terrestrial fungi. Recently, marine microscopic fungi have been reported from molecular surveys (Hassett et al., 2019), and are widespread in the Arctic. Among these are chytrids that likely parasitize diatoms. These appear near the end of the spring diatom bloom, suggesting a major role in carbon and energy cycles in the Arctic.

Incertae sedis

Other small heterotrophic flagellates are ubiquitous in the ocean and often account for non-negligible contributions to gene surveys in the Arctic. These include unrelated taxa that currently cannot be placed into larger universal phylogenies and are referred to as *Incertae sedis*. Among these is the bacterial predator *Telonemia* (Fig. 5C) and a tiny (1–2 µm) flagellate in the *Picozoa* (Thaler and Lovejoy, 2015), which likely subsists on viral particles and organic matter polymers.

Bacteria and Archaea

Bacteria and Archaea are responsible for remineralization of nutrients and play essential roles in the global Nitrogen, Sulfur and Carbon biogeochemical cycles. The biodiversity of Bacteria and Archaea has only been appreciated since the advent of the molecular era. To date, at least one bacterial clade seems to be specifically adapted to Arctic organic substrates (Colatritano et al., 2018) and, as with other plankton in the Arctic, it is reasonable to assume that more arctic ecotypes and species of Bacteria and Archaea will eventually be discovered.

Cyanobacteria

Cyanobacteria are true bacteria, lacking a well-defined nucleus and membrane-bound organelles. With some exceptions in warm tropical seas, planktonic cyanobacteria are >2 µm picoplankton. The two most common planktonic genera have well-defined latitudinal limits. The smallest *Prochlorococcus* is rare above 40° latitude. *Synechococcus* is distributed further north, but is extremely rare in Arctic Ocean where the green alga *Micromonas* occupies the picophytoplankton niche (Li et al., 2009). *Synechococcus* and most other cyanobacteria can be counted using epifluorescence microscopy or flow cytometry because of the presence of bright fluorescing biliproteins. The disappearance of these cells detected using flow cytometry crossing the polar front in both the Arctic and Antarctic is striking (Dubreuil et al., 2003). Occasionally freshwater forms of *Synechococcus* are reported offshore in the Arctic, but they are unable to grow in marine waters and are likely washed in from large rivers surrounding the Arctic Ocean (Vincent and Quesada, 2012). The lack of *Synechococcus* in Arctic marine waters is possibly due to temperature limitations with growth rates lower than losses from grazing.

Heterotrophic bacteria

Bacterioplankton are essential for degrading organic carbon in the open ocean, including the Arctic. The distributions of major Bacteria clades were recently reviewed in Pedrós-Alió et al. (2015), who found that at the level of Class, Arctic bacterioplankton were similar to other open oceans. Some evidence suggests that higher proportions of *Betaproteobacteria* and *Gammaproteobacteria*, compared to *Alphaproteobacteria*, are indicative of recent ice cover. However, as with other Arctic organisms, at the species level (inferred from 97% to 99% similarity of 16S rRNA genes). Arctic bacterioplankton are distinct from Global Ocean populations outside of Polar Seas (Ghiglione et al., 2012), and arctic-specific clades of major lineages are known.

Archaea

Archaea superficially resemble bacteria in that they have no membrane-bound organelles. Early work investigating 16S rRNA genes first established them as a separate domain of life and later they were found to be omnipresent in world oceans, including two major lineages (Crenarchaeota MGI, now Thaumarchaeota and Euryarchaeota) in the central Arctic (Bano et al., 2004). Marine Archaea are involved in several key biogeochemical cycles, for example, in the Arctic Thaumarchaeota can take up urea and oxidize ammonium to nitrite, which is then converted to nitrate (Alonso-Saez et al., 2012). Metagenomic studies, where entire microbial communities are sequenced and then reconstructed using bioinformatics tools, have begun to elucidate some of the functions of what are referred to as Marine Group (MG) II and MG III Euryarchaeota, which tend to occur at low abundance and evade cultivation. MG II, which has been proposed as a candidate Order level lineage (*Canidatus* Poseidoniales), are considered photoheterotrophs, harvesting light using proteorhodopsin (Rinke et al., 2019). MG III Euryarchaeota are thought to specialize in the degradation of high molecular weight organic compounds. An early study using high throughput sequencing found that MG I (Thaumarchaeota) was overall the most abundant group in the Arctic Ocean (Galand et al., 2009). MG III Euryarchaeota were more abundant in deep-water masses and represented the largest archaeal group in the deep Atlantic layer of the central Arctic Ocean. Coastal surface waters, in turn,

harbored more MG II Euryarchaeota. The MG II sequences that dominated surface waters differed from the MG II sequences detected in deep waters, suggesting functional differences in closely related groups.

Summary Statement

Overall Arctic plankton tend to have pan-arctic distributions and a high proportion of endemic species, and Arctic Biome should be considered as a major contributor to global biodiversity.

Sea ice algae Microalgae (mainly diatoms) living inside brine channel system.

Abstract

Arctic sea ice provides habitat for unique, highly specialized communities ranging from viruses, bacteria, and microalgae to seals and polar bears. Life inside the sea ice occurs in the salty brine channel system, and its environmental settings (mainly temperature, salinity, and light) control the biodiversity and the seasonal cycle of the associated flora and fauna to a very large extent. An overview of the associated diversity is provided, followed by a discussion of the seasonal succession contrasting activity and controls for fall/winter, spring and summer. The biological relevance of ice formation and ice melt are discussed. Sea ice habitat is not isolated from water column and sea floor habitats. In contrast strong biological coupling occurs through the migratory life cycles of benthic invertebrates and the vertical flux of organic matter in the form of living algal aggregates or fecal pellets even down to water depths exceeding 1000 m. Implications of observed climate change effects and associated changes in the physical properties of sea ice are discussed and the need for further research is highlighted.

Introduction and Outline

While polar oceans appear to humans as rather hostile environments, they are the habitats for thousands of species living at the sea floor (benthos), within the water column (plankton and nekton) and sea ice (sympagic communities). Sea ice (Fig. 1) itself is a unique feature in polar seas and, although they look similar, Arctic and Antarctic sea ice are distinctly different in their physical and chemical characteristics (Eicken, 2003). This article will thus only focus on Arctic sea ice, as conditions and biological properties in Antarctic sea ice are different. Habitat properties vary with the age of the sea ice and the types of ice formation, all of which causes differences in sea ice biota in different parts of the Arctic. This article will start with an introduction to the macro- and microscale properties of Arctic sea ice, its seasonal and regional occurrence as well as its main physical properties. We will explore the challenging living conditions experienced by sea ice biota, followed by an overview of the known biological diversity of Arctic sea ice biota. A discussion of the adaptations of ice biota is followed by discussion of the seasonal development of the ice biota and their role in the Arctic marine food web. Finally, the implications of climate change effects on sea ice biota are reviewed.

Macro- and Microscale Habitat Properties of Sea Ice

Seasonal Changes in Sea Ice Extend Across the Arctic Ocean

The extent and concentration of Arctic sea ice may be assessed these days for any day of the year based on high quality remote sensing data (**Fig. 2**) (Stroeve et al., 2011). This information is freely available from various websites (see Relevant Websites). Time series observations of sea ice extent typically go back to 1979, when the first observations were made public. The long term mean conditions (climatology) demonstrate a large seasonal variation along a reduction due to climate change (Polyakov et al., 2017). Typically, Arctic sea ice reaches its maximum in March. Until recently, this maximum ice extent covered to 14–15 million km². Summer ice melt greatly reduces the ice extent, reaching a minimum in September. Until about 10 years ago typical summer values averaged around 7 million km². However, over the last 10 years summer ice extent has been greatly reduced due to accelerated melting rates and later formation dates. Today Arctic sea ice covers only 3.5–5 million km² in summer (**Fig. 2**). The seasonality of sea ice cover is driven by the balance between formation and thickness growth of sea ice during the dark, cold winter months and melting during the midnight sun summer period. Sea ice surviving the summer months and starting a new freezing cycle is called second- or multi-year ice. The thickness of the multi-year ice varied historically between 2.5 (summer) to ca. 3.5 m (winter) in undeformed areas. Pressure ridges built by colliding ice floes can greatly exceed these values and ice drafts of over 30 m have been reported. The drastic loss of summer sea ice has caused a large reduction in multi-year sea ice. This has been replaced by newly forming first-year sea ice over vast areas of the Arctic (**Fig. 2**). First year ice (both land-fast and pack ice, see below) is slightly more salty than multi-year sea ice (providing more inhabitable brine space) and also thinner than multi-year ice (typical winter thicknesses < 2 m).

The sea ice cover of the central Arctic Ocean consists of individual free drifting units (see below). Two major drift patterns exist: the Transpolar drift transports sea ice across the Arctic Ocean from the Russian shelves to the North Atlantic in ca. 3–5 years, while the Beaufort Gyre is a clockwise wind-driven circulation pattern, in which one rotation of the ice pack requires about 10 years. In

Fig. 2 Remote sensing of the seasonally changing sea ice extent in 2018. (A) Winter sea ice extent in March 2018. (B) Summer sea ice extent in September 2018. Source: <http://marine.copernicus.eu/services-portfolio/access-to-products/>.

contrast to pack ice, land-fast ice is attached to the coast and does not drift with the wind and/or the ocean currents. It is formed close to land and can extend for a few to dozens of kilometers from the shore line onto deeper parts of the shelf. Most of the fast ice forms annually and melts completely in spring/summer. Along the boundary areas between fast and pack ice, open water areas exist even in winter. These are termed “coastal flaw lead polynyas.”

During ice formation, several distinct growth stages can be distinguished, all of which are relevant to our understanding of the development of sea ice biota. As air temperatures decrease, sea water cools to its freezing temperature which, depending on salinity, is between -1.4 and -1.8 °C. Further cooling initiates ice formation in the form of freely floating ice crystals which accumulate at the surface due to their density being lower than that of sea water. However, these are resuspended in the water column through vertical mixing by wave action. Under calm conditions however, a thin skin of ice (nilas ice, Fig. 1) can cover dozens of km² of the ocean surface, while under wavy conditions, these sheets are broken up into small pieces which become rounded through constant collisions, giving them the distinctive shape of pancake ice. In the initial stages, ice crystals grow individually in different orientations and can collect particles while moving through the water column. These particles include sediment and biota, and they become incorporated into the growing ice sheet. Further cooling consolidates the pancakes into large ice cakes or ice floes and ice growth no longer occurs through mixing of individual ice crystals at the surface but rather through new ice growth at the bottom of the existing ice floes. Under such conditions, ice growth leads to differently shaped ice crystals at the bottom of the ice.

As mentioned above, ice crystals suspended in the water column are mixed through wind and wave action through the uppermost meters of the water column before becoming consolidated into nilas or pancake ice. During the suspension process sticky particles such as sediment grains, bacteria, and microscopic algae become attached to the ice crystals and float with the ice into the ice sheet. This process explains how developing sea ice becomes loaded with microscopic life forms. Specifically, bacteria and algal abundances can be enriched by several orders of magnitude within the growing sea ice, compared to their concentrations in the underlying sea water (Gradinger and Ikävalko, 1998). However, not all these organisms survive within the sea ice, so local selection leads to distinct communities that differ in relative composition compared to what is found in the water column below. Part of the seeding of ice might also come from other ice floes surrounding the growing ice—explaining the existence of endemic (only in one habitat/region) occurring species of algae and small crustaceans and nematodes in Arctic multi-year ice regions.

The Microscale Brine Channel System Within Arctic Sea Ice

The small remaining fraction of salty water (brine) that is trapped between the ice crystals is critically important to our understanding of the relevance of sea ice as a habitat. This salty water forms the so-called brine channel system (Fig. 3) (Krembs et al., 2000). The size of the saltwater filled brine pockets and channels are mainly in the μm to mm size range, limiting the ability of larger organisms to live there. The volume and salinity in the brine channels is largely determined by sea ice temperature and the total amount of salt remaining in the system (Eicken, 2003). Under typical summer conditions, the brine volume in sea ice may reach values approaching 25% of the entire ice volume at the bottom of the ice (where it is relatively warmest and most salts are contained), while in the ice interior and at the top in winter sea ice (very cold, low remaining salt content) values are generally below 5%. Ice temperatures are often close to atmospheric temperatures at the top of the ice, while they are close to the freezing point of water (see above) at the bottom. Very cold temperatures cause very high brine salinities and values over 150 have been observed, and these hypersaline waters cause enormous osmotic stress on sea ice organisms, specifically in the coldest uppermost parts of the ice. In contrast, near constant temperatures close to the freezing point foster near sea water salinities at the bottom of the

Fig. 3 Visualization of the Arctic brine channel network accomplished by pouring red dye onto the bottom block of sea ice—Please note that the red dye penetrates deeply into the interconnected brine channels for several dm. Picture taken in Svalbard, fast ice system.

ice, making the ice bottom layers the most favorable habitat for organisms. These favorable conditions include (a) relative warmth, (b) salinities close to ocean water levels, (c) provision of large brine volumes and (d) easy access to nutrients or seeding populations from the water below. It therefore should not come as a surprise that the highest abundances of any organisms in Arctic sea ice are found at the bottom of the ice, often exceeding values in the ice interior by several orders of magnitude (**Fig. 4**) (e.g., [Gradinger, 1999](#)).

The above short introduction into the macro- and microscale characteristics of Arctic sea ice demonstrates that sea ice is not a homogeneous biological habitat. Rather, sea ice is quite variable on scales from mm to km, fostering considerable biological

Fig. 4 Ice floe turned around by icebreaker action, showing the dark brown bottom layer of sea ice thickness. Diameter of the ice floe ca. 3 m.

variability. Consequently, study of the biota associated with coastal fast ice does little to aid our understanding of deep Arctic Ocean systems with very different ice characteristics.

Diversity of the Arctic Sea Ice Biota

Although great progress has been made in our understanding of the diversity and activity of Arctic sea ice biota, it is clear that inventory of known species remains incomplete and is likely to increase dramatically during the coming decades. By now we know that the sea ice brine channel system is the habitat for several thousand species of viruses and bacteria, between 1300 and 1500 species of microalgae and small protozoans, and about 40 different species of small metazoans (sea ice meiofauna) (Bluhm et al., 2011). Factors constraining the presence and abundance of sea ice biota are linked to the physical environment (see above) as well as the strong seasonality in biological processes (see below).

Brine channel system dimensions provide an upper limit for the size of organisms living within the ice. No limitations exist for the tiny bacteria and viruses, and for most of the microalgae. However, metazoans are often excluded from the brine channel network due their larger size, specifically the large (several mm to over 1 cm long) herbivorous crustaceans (copepods of the genus *Calanus*) that dominate the water column below. To a large extent, this grazer exclusion explains why the growth of primary producers (algae) within the ice is not controlled by grazing but by physical variables such as light, temperature, brine salinity, brine volume fraction, and by availability of plant nutrients (mainly nitrate), coming from the water column below.

Microalgae (Poulin et al., 2011) are likely the best studied component of the sea ice biota (Fig. 5) in terms of biomass, diversity and regional differences. The highest number of species and highest biomass are likely contributed by diatoms. All diatoms are characterized by a silicate frustule, their ability to photosynthesize, their complex life cycles and the large variation in their shapes and forms. Within Arctic sea ice, algal communities are often dominated by relatively large colonial diatoms, with taxa such as *Nitzschia frigida* and various species of *Fragellariopsis* occurring in the brine channels in all parts of the Arctic. Some of the diatom species can form morphological resting stages (called spores), but many species do not. Unique to the Arctic are curtain-like diatom colonies hanging down from the ice-water interface to the water column below. These brownish colonies make exceed lengths of several meters and are formed by a single species called *Melosira arctica*. Long chains of cells of this species are intertwined and embedded in a slimy matrix, ensuring the stability of the curtains. It is believed that the ends of the chains extend into brine channels at the ice bottom, using slime as a glue to ensure attachment to the bottom of the ice.

Diatoms are not the only phototrophic inhabitants inside the sea ice. There are perhaps hundreds of species of flagellated taxa including haptophytes, prasinophytes, dinophytes, and euglenophytes that also inhabit the ice interior. Many of these taxa are not obligatory phototrophs. A whole range of different nutritional modes has been observed, ranging from photo- to mixo- to obligatory heterotrophic species. Some of the heterotrophic flagellates (large euglenophytes such as *Anisonema* sp.) feed directly on ice diatoms, while others form part of the microbial food web, recycling organic matter inside the ice by feeding on bacteria.

Fungi have also very recently been discovered in Arctic sea ice (Hassett et al., 2019). One group called thraustochytrids are parasites, attacking specific diatom species. However, research on these fungi is still in an early exploratory phase.

Sea ice heterotrophs inside the brine channels include small flagellates (size range of ca. 5–100 μm), ciliates (size range of 20–200 μm) and small metazoans (typically above 70 μm in size). For metazoans inside the ice, different water depths beneath the ice translate to large differences in species composition (Bluhm et al., 2018). In nearshore areas where water depth is < 100 m (often in fast ice areas), juvenile stages of benthic (bottom living) invertebrates such as polychaetes, mollusks and gastropods are released

Fig. 5 Example of a sea ice brine community dominated by diatoms (picture taken in the Bering Sea, pack ice, March 2010). Size of the diatom cells ca. 40–80 μm .

into the water column and swim towards the ice system to feed on the high abundance of diatoms in the ice bottom layer. Other taxa such as nematodes, acoel turbellarians, rotifera and copepods are found in all parts of the Arctic. Most of these taxa are herbivores, feeding on ice algae. However, there is an ice-inhabiting jellyfish (*Sympagohydra tuuli*) that appears to be the top predator in this food web, ingesting a wide range of other sea ice meiofauna.

Similar to *Melosira arctica*, no size limitation exists for animals using the bottom of Arctic sea ice as a substrate. Here Arctic ice endemic species of amphipods (*Apherusa glacialis*, *Onisimus* sp., *Gammarus wilkitzkii*) are found from the nearshore to the deep Arctic basins, living in permanent association with sea ice (Hop and Pavlova, 2008). Although closely related genetically, these amphipods inhabit different ecological niches. *A. glacialis* is mainly herbivorous; *Onisimus* spp. are omnivores and *Gammarus wilkitzkii* is a carnivore. *G. wilkitzkii* not only preys on other ice associated amphipods, but it also harvests pelagic crustaceans such as *Calanus* spp. if they stray too close to the bottom of the ice where *C. wilkitzkii* lives.

Fish inhabit the ice water interface as well, mainly *Boreogadus saida* (Arctic cod). This species uses the sea ice as a hideout from potential predators such as birds or seals, while feeding on ice-associated or pelagic crustaceans. Not all *B. saida* populations are ice associated. This fish also occurs in high abundances in open Arctic areas.

Sea ice is not only a habitat for marine organisms. Arctic birds, seals and the polar bear use sea ice for resting, travel, reproduction and (in the case of polar bears) as a hunting platform. Not all ice related seals feed directly on the ice-associated fauna as does the ringed seal, for example. Walrus and bearded seals use sea ice as a platform for reproduction and to dive down to the sea floor to feed on benthic communities. Polar bears are likely the most charismatic megafauna associated with sea ice. In conclusion the Arctic ice habitat plays an essential role for a variety of marine mammals.

Seasonal Development of the Arctic Sea Ice Biota

Fall/Winter

From the human perspective fall/winter are the most hostile months in the Arctic. Air temperatures drop below -30°C , causing fast ice growth, high brine salinities and adding snow on top of the ice. Periods without sun light vary dependent on the latitude, but time spans of complete darkness in Arctic Seas range from 3 to 5 months with the only light coming from the moon or from bioluminescence. Light levels are so low that no photosynthesis by algae occurs.

During winter, the abundance of organisms in the ice and in the water column are at a minimum. Some species of diatoms overwinter by reducing their metabolism to an absolute minimum, which allows them to rest for months, relying on their nutritional reserves in the form of e.g., lipid droplets. Other organisms switch to heterotrophy by ingesting bacteria or detritus (dead organic matter). However, it should be noted that winter is the least studied period of the annual cycle due to the difficulties of winter-season research in Arctic waters. Therefore, it must be said that the winter biological adaptations of the ice flora and fauna are poorly investigated.

Within the ice, very cold temperatures lead to high brine salinities that induce osmotic stress in sea ice biota (e.g., Kiko et al., 2008). Different metabolic pathways have evolved to acclimate these organisms to varying salinities. These adaptations range from ion pumps to the production of organic chemicals called osmolytes, both of which have been studied in sea ice algae and ice inhabiting metazoans. However, these protective measures come at a metabolic cost, so growth rates of these organisms decline sharply as they are exposed to higher salinities. The highest salinities that sea ice biota are able to survive range from 80 (for metazoans) to 150 (for sea ice microalgae).

Spring

After months of darkness, the return of sun light marks the beginning of early spring. Arctic sea ice algae are among the best adapted species on Earth to photosynthesize under very low light intensities. Even 0.1% of the surface light intensity (e.g., at surface above $1000\ \mu\text{mol photons m}^{-2}\text{ day}^{-1}$) on a sunny day is sufficient to start ice algal growth. Low grazing pressure, adequate supply of inorganic nutrients and increasing light intensities cause massive bursts of development of ice algae at the bottom of the Arctic sea ice during the few weeks in early spring. The timing of the bloom varies with latitude. For instance the onset occurs in March in the Bering Sea and in April/May in the Beaufort Gyre. In addition to the latitudinal gradient, local conditions such as nutrient load in the water column or light reducing thick snow layers on top of the ice cause small to large scale variations in the ice algal biomass accumulation.

In the field, maximum ice algal concentrations in the lowermost 1 cm of the sea ice can exceed concentrations found in the water column by 1–3 orders of magnitude. It thus is no surprise that in nearshore waters, juvenile stages of benthic invertebrates can dominate the meiofauna community for several weeks (until the juveniles go back to the sea floor or the ice melts). Feeding on dense masses of sea ice diatoms allows for much faster growth than feeding on the less concentrated phytoplankton biomass. Reproductive events of the sea ice meiofauna are also linked to the ice algal bloom. Small copepod nauplii or egg cases or small juveniles of ice nematodes can be found in the ice in spring. At the bottom of the ice, ice amphipods such as *A. glacialis* and *Onisimus* spp. graze on the ice algal bloom. Amphipod fecal material (fecal pellets) is very dense and sinks quickly to the sea floor, providing the first fresh pulse of organic matter to the benthic fauna since the previous summer.

Summer

Continued solar heating transforms the sea ice habitat from spring to the summer melting stage. Increased surface heating opens up the brine channel network causing flushing of melt water through the sea ice and also melting of the bottom layer. With the flushing and/or the melting, a sudden release of accumulated organic biomass in the form of the ice algae occurs. Algae, including the under-ice species *M. arctica*, clump together and form larger aggregates that sink to the sea floor at rates of hundreds of meters per day. This input provides high quality undigested food to the benthic fauna, and benthic holothurians, for example, have been observed feeding on *M. arctica* aggregates at water depths exceeding 1000 m (Rybakova et al., 2019).

Melting not only reduces the abundance of all ice related organisms, but low salinity accumulations can also cause osmotic stress. Here ice flora and fauna respond by moving to deeper water. Here they settle on ice pressure ridge keels with depths exceeding 10 m, or some enter a pelagic life stage (as typical for Antarctic sea ice flora and fauna) (Gradinger et al., 2010).

Consequently, summer is not necessarily the peak time of ice related biological productivity. Rather, it is the early spring months right after the return of sun light, during which most biological activity occurs at the bottom of the ice, not visible from the surface. This is in striking contrast to processes in the water column. Here the melting of the sea ice in the marginal ice zone actually stimulates phytoplankton growth in the water column by increasing light availability as the ice melts. There is also less mixing of waters with different densities. Such strong blooms of phytoplankton in the marginal ice zone can be detected from space by changes in ocean color and often occur earlier than mass developments of phytoplankton in seas south of the ice covered regions.

In conclusion, sea ice harbors a diverse community and a very active dense layer of primary producers (often dominated by diatoms) in the bottom few cm of the sea ice, close to the ice-water interface. Annual estimates reveal that the ratio between sea ice algal production and total Annual Arctic Ocean production varies with region. In seasonally ice-covered coastal seas with shorter ice cover and longer open water periods, ice algae may contribute ca. 5–25% of biological productivity. In the central Arctic Ocean, permanently covered by sea ice, this value increases to ca. 50% (e.g., Gradinger, 2009). Through the ice-based food web including amphipods and fish, part of the organic matter produced by ice algae contributes substantially to the nutrition of seals, birds and polar bears (e.g., Cusset et al., 2019).

Climate Change and the Arctic Sea Ice Habitat

The physical properties of Arctic sea ice have received considerable scientific and public attention over the last few decades, using those as one of the canaries in the coal mine to reveal climate change. Substantial loss of summer and multi-year sea ice, increased dominance of thinner first year ice, later ice formation and earlier ice melt have been documented around the Arctic. All of those factors have biological consequences, some of them obvious, some of them cryptic, thus far.

Obviously, loss of sea ice habitat causes severe stress on sea-ice organisms, from diatoms to seals and walrus. The future existence of this sea-ice biota will depend on whether they will be able to follow the receding ice edges and stay with the ice (e.g., ringed seals). This is not the case for all species. Walrus, which are bottom feeders, cannot dive to the vast depths of the central Arctic Ocean to get to their benthic food sources and ice loss on the shallower seas will leave them without their feeding platform. Alternatively, pelagic or benthic life stages might be able to survive without sea ice. This is a currently anticipated outcome for at least one amphipod species formerly considered to be ice endemic (*Apherusa glacialis*).

The loss of the contribution of sea ice algae to total algal productivity will likely be compensated by increased water column (phytoplankton) productivity. Indeed, expeditions in the Beaufort Sea and in the Nansen Basin revealed substantial under-ice algal phytoplankton blooms, supported by high light intensities allowed by melting snow and large leads of open water. Of greater biological concern is the timing of ice melt associated with ice algal bloom development. As specialists, ice algae can grow under very low light intensities, thereby forming the foundation of the sea-ice based food web. The biology of these algae is also closely coupled to water column and sea floor biological processes through export in the form of fecal pellets or living algal aggregates. Very early ice melt might reduce this input by reducing the spring ice algal blooms. A delay in the commencement of phytoplankton growth could lead to extended periods of low food supply to the sea floor fauna beyond the already long Arctic winter. Only future observations will provide answers concerning the responses of Arctic sea ice habitat and its associated biota to future environmental changes. It appears certain that changes in biological diversity, production and connectivity could lead to unanticipated cascading ecological effects.

Abstract

Plant life around ice sheets and glaciers develops in the process of primary succession by means of a gradual colonization of the barren substrate by cyanobacteria, lichens, bryophytes and vascular plants. These plants create initial plant communities in the forelands of Arctic glaciers; under such harsh conditions, particularly cryptogamic species, create biological soil crusts. The number of cryptogamic species colonizing freshly deglaciated forelands exceeds the number of vascular plant species. Cryptogams that initiate the colonization process in the forelands modify the edaphic and microclimatic conditions and favor the growth of other taxa that create the next successional community and may replace previous species by competition. Currently, due to the fast rate of retreat of glaciers, this process is easy to observe. The gradual deglaciation of Arctic landscapes over more than one century, which started since the end of the Little Ice Age at the end of 19th century, gives a unique opportunity to investigate this process in detail. At the beginning of 20th century the primary succession process was described as linear and directional, ending in a final climax community. However, this view is questioned today. Primary succession is no longer necessarily considered to be a linear and directional process due to species turnover, and species equilibrium is rarely reached. Plant communities that develop in glacier forelands exhibit the properties of near-climax communities.

Introduction—What Is the Primary Succession Process?

The succession process is defined as species change over time and it is divided into two types: primary succession occurring on substrates with no previous biological life; and secondary succession happening on substrates with a biological legacy that has been disturbed. The processes of primary succession on a barren substrate by living organisms are rarely observed in nature. There are only a few places where the conditions for the existence of these phenomena are possible: areas submerged with lava after volcanic eruptions, volcanic islands emerging from the sea, and areas recently exposed from beneath the ice. These provide a natural laboratory where we can trace ecosystem formation from the earliest stages. Primary succession begins when microorganisms, plants and animals start to colonize a new substrate. Here we will focus on plant succession and vegetation development in glacier forelands in the Arctic.

At the beginning of 20th century, Clements (1916) proposed an approach in which succession has a linear and directional character and ends in a final climax community. This view has been questioned by Gleason (1917, 1926) and further elaborated by Eglar (1954), Drury and Nisbet (1973) and Whittaker (1974). Currently, primary succession is not always considered as a linear process due to the turnover of the component species. Therefore the process rarely reaches species equilibrium (Walker and del Moral 2003).

Climate change is currently driving the expansion of ice-free areas in glacier forelands, indicating the need for research on the primary succession. Consequently, Arctic regions offer perfect opportunities for studying this processes on the freshly deglaciated areas gradually inhabited by different groups of organisms: microorganisms, lichens, bryophytes and vascular plants (Frenot et al.,

1998). The process of colonization depends not only on availability of diaspores of surrounding vegetation (Bullock et al., 2002; Jones and del Moral, 2009; Del Moral and Erin, 2004; Řehounková and Prach, 2006), but also on the various abiotic factors that characterize the habitat (Matthews, 2008), and geomorphological processes shaping the surface after the disappearance of ice. As a result, interdisciplinary research combining botany, geomorphology, meteorology and soil science is needed to provide a detailed knowledge of primary succession. Currently, research on the succession on glacier forelands is still needed because of the rapid growth of ice-free areas and the increasing rate of melting glaciers due to climate change (Laspoumaderes et al., 2013). There are still mechanisms and environmental factors influencing these processes that have not yet been investigated (Walker and del Moral, 2003; Prach and Rachlewicz, 2012).

Climate Change and Glacier Recession

The Arctic is one of the regions most threatened by climate change. Global system changes have happened regularly throughout the history of Earth and are not a new phenomenon (Huntley, 1991), but in polar regions the main problem is the current rate of climate change, which is so fast that these ecosystems may not be able to adapt to all shifts in a natural way (Duarte et al., 2012).

In recent decades global climate changes, including a gradual temperature increase, have been widely documented and monitored (e.g., Hansen et al., 2012; Pachauri et al., 2014). Currently, the Arctic temperature rise is the greatest (Menne and Kennedy, 2010): from 1995 to 2005, the average annual temperature has increased by more than 1°C compared to the average for the period 1951–90 (Przybylak, 2007). During the years 1961–2004, the Arctic regions (without the contribution of ice sheets in Greenland) were the second main water sources responsible for increasing global sea level (Kaser et al., 2006; Lang et al., 2015). Moreover, the ice loss in the Arctic has reached c. 50% of all ice caps and glaciers (Gardner et al., 2013). Many reports based on climate models (Holland et al., 2010; Vavrus et al., 2012; Stocker et al., 2013) predict a further rise of temperature, humidity and cloud cover, and a decrease of ice cover, with an enormous influence on terrestrial and marine habitats and their ecological dynamics (Grémillet et al., 2015). These will result in, for example, a further expansion of shrubs and forest into the north, permafrost degradation, and glacier regression (Stocker et al., 2013; Pachauri et al., 2014; Jorgenson et al., 2015).

Since the beginning of the 20th century, documentation of glacier ranges and thickness changes is wide ranging and includes both polar regions and mountains. Data collected within the international monitoring of glaciers (World Glacier Monitoring Service) clearly shows a loss of glaciers on all continents, progressing especially in the second half of the 20th century (Fig. 1; Zemp et al., 2008; Nuth et al., 2013).

History of Primary Succession Studies in the Glacier Forelands

The history of research on primary succession of vegetation in the glacier forelands started in the early 20th century. However, the majority of these studies came from the last few decades because of the accelerated rate of glacier recession worldwide, which strongly effects recruitment of glacier foreland species (Mondoni et al., 2015).

Fig. 1 View of retreating glacier in Ringhornsdaalen. © P. Wietrzyk-Pelka.

The first published observations from Glacier Bay, Alaska referred to the characteristics of ecological conditions on the forelands of retreating glaciers (Cooper, 1923a), as well as a description of the plant communities in different substrate ages and the adaptation strategies of pioneer species (Cooper, 1923b). During these studies permanent sample plots were established to follow the succession process in subsequent years (Cooper, 1931, 1939). Research in Glacier Bay also included the effect of vegetation on soil development within the glacier marginal zones (Crocker and Major, 1955). The study of plant succession on European mountain glaciers forelands began in the middle of the 20th century (Palmer and Miller, 1961; Worsley and Ward, 1974; Sommerville et al., 1982). Even today, mountain glacier forelands are of great significance for research on various aspects of primary plant succession (Erschbamer et al., 2008; Robbins and Matthews, 2009; D'Amico et al., 2014; Mizuno and Fujita, 2014). Intensive studies have also been carried out in the polar regions. Most data from the Southern Hemisphere comes from the Maritime Antarctic, West Antarctica (Olech, 1996; Olech and Massalski, 2001; Casanova-Katny et al., 2014) and the Subantarctic Kerguelen Islands (Frenot et al., 1998), as well as from the Northern Hemisphere, especially from the Canadian Arctic (Chapin et al., 1994; Jones and Henry, 2003; Fastie, 2009; Mori et al., 2017), and Svalbard, where research on primary succession of vegetation has been initiated by Kuc (1964). A significant portion of the world's latest research on primary succession on glacier forelands comes from Ny-Ålesund region (NW coast of Svalbard) where the following topics have been covered: plant community evolution (Hodkinson et al., 2003; Moreau et al., 2005, 2008), pioneering species (Nakatsubo et al., 2010), and species ecology (Nakatsubo et al., 2005; Uchida et al., 2006; Yoshitake et al., 2007), as well as the role of soil microorganisms (Bekku, 2004), including mycorrhizal fungi (Cázares et al., 2005; Fujiyoshi et al., 2010). Research has been conducted in other parts of Svalbard by Tishkov (1986), Ziaja and Dubiel (1996), Fabiszewski (1975) and Wojtuń et al. (2008). However, most research on primary succession in Svalbard has concentrated on the transformation of vascular plant communities (e.g., Pirożnikow and Górniak, 1992; Nakatsubo et al., 2010; Prach and Rachlewicz, 2012; Yoshitake et al., 2011), or their interactions with mycorrhizal fungi (Těšitel et al., 2014; Davey et al., 2015). Other components of the vegetation of glacier marginal zones (in particular bryophytes and lichens), were often overlooked or treated in a general way, without detailed species identifications. Spore-bearing organisms, bryophytes and lichens, are the main tundra component and also often the dominant species in initial communities developing in glacier forelands. This indicates their great importance in the primary succession process (Wietrzyk et al., 2016).

Main Colonizers

Cyanobacteria

Cyanobacteria are dominant in the cold polar ecosystems of the Arctic, occurring in extremely cold habitats, such as glacier foreheads, glacier forelands, glacial rivers, and lakes (Fig. 2). They are one of the first colonizers of glacier forelands from which ice cover has retreated, where they play an important role in carbon and nitrogen supplies. The ecophysiological features of cyanobacteria that contribute to their success and domination include an ability to grow in a wide range of temperatures, tolerance to the stresses of drying, freezing and salinity, different adaptation strategies against high levels of solar radiation (including ultraviolet radiation) in vulnerable habitats, and acclimation to shaded environments (Vincent, 2000). During the 19th century it was discovered that cyanobacteria occur in small melt cavities filled with water (cryoconite) on the foreheads of glaciers. Previous research has shown that this specific micro-habitat is inhabited by filamentous cyanobacteria of the genera *Phormidium*, *Lyngbya*,

Fig. 2 Cyanobacteria of the genus *Nostoc* in microscopic section. © P. Wietrzyk-Pelka.

Microcoleus, and *Nodularia*. Furthermore, kettles, ponds, rivers and smaller glacial streams formed by geomorphologic processes are very rich in cyanobacteria from the orders *Oscillatoriales* and *Nostocales* (Vincent, 2007). Their presence is connected with the early stages of primary succession, when the substrate exposed by retreating ice is devoid of nutrients. Presumably, cyanobacteria species originally transported by glacial waters are deposited on various types of foreland substrate, being one of the first organisms on the barren surface and also having the ability to assimilate atmospheric nitrogen. Thus, they play an important role in the nitrogen availability for plants in these habitats (Bliss and Gold, 1994) and their presence triggers soil-forming processes; this increase in biogenic elements facilitates the subsequent colonization of bryophytes, lichens, and vascular plants on glacier foreland.

Lichens

Lichens as cryptogamic organisms are one of the main components of tundra communities in Arctic regions. Early stages of lichen succession can be observed in the foreland of glaciers, where thanks to the early presence of prokaryotic and eukaryotic algae, the lichenization of both components, fungus and algae, occurs. The species of lichens colonizing glacier forelands can be divided into two groups: epilithic lichens, which overgrow gravel and rocks, and epigeic lichens, which, together with algae, bacteria and fungi, form biological soil crusts (Fig. 3; Belnap et al., 2001). Of all lichens, a special role is played by species with a cyanobacteria component; their ability to utilize atmospheric nitrogen enhances the substrate with nitrogen. The lichen thalli, supported by algal mats, also bind large amounts of organic carbon as a result of photosynthesis, and after their decomposition, contribute to the enrichment of the initial soil. The dominant species are from the *Collema* genus, which occur both close-in and distant from glacier foreheads. Species of this genus are cyanolichens (the hosts for cyanobacterial symbionts) and this feature influences their colonization potential (Sancho et al., 2011). Recent research shows that one of the main factors limiting the occurrence of epigeic lichens on glacier forelands is the stability of the substrate. In the case of epilithic lichens, colonization may start earlier due to their more stable substrate (especially regarding large block of rocks), but colonization of the soil by epigeic lichens is not as long as that of epilithic species, however, in relation to bryophytes or algae it requires a longer period than one season of the Arctic summer (Longton, 1988). Glacier forelands do not represent a homogeneous substrate; along the whole of their length the geomorphologic processes cause various disturbances making substrates very unstable, especially in areas with a steep slope or river activity. Surface erosion impedes epigeic lichen colonization. Even the presence of epilithic lichens may be limited by rock movement or surface washing by glacial rivers; in such disturbed and wet areas, bryophytes are usually more apparent.

Bryophytes

Unlike lichens, bryophytes (mosses and liverworts) show a much faster growth rate, and produce a greater biomass (Longton, 1988). In glacier forelands subjected to strong erosion, for instance the activity of glacial rivers, bryophytes are able to colonize the substrate in a short time, tolerating increased soil moisture levels (Fig. 4; Walker et al., 2001; Wietrzyk et al., 2016). In addition to cyanobacteria, bryophytes are the organisms that are able to occupy habitats closest to glacial ice margins. Unlike epigeic lichens, they have developed a system of rhizoids that function as a root, thereby surviving in periods of high surface water and being better

adapted to a less stable ground. Recent research has identified bryophyte species growing close to glacial margins (Wietrzyk et al., 2018) that are also usually commonly found in mature tundra communities, such as *Bryum pseudotriquetrum*, *B. caespiticium*, *Calliergon sarmentosum*, *Ditrichum flexicaule*, *Encalypta alpina*, *Pohlia cruda*, *Polytrichum piliferum*, and *Sanionia uncinata*. Their presence in the coldest and most unstable regions of the foreland indicates their particular adaptation to extreme conditions.

Vascular Plants

Vascular plants appear to be the final organisms to colonize glacial forelands, after the barren substrate has already been significantly transformed by cryptogam colonization and soil-forming processes. However, studies have shown that vascular plants are usually not the last group of colonizers, and some species may even appear as first colonizers (Fig. 5; Wietrzyk et al., 2016). The plants' life forms and their spreading methods also influence the colonization potential of individual species. All monocotyledon plants recorded in the early and later stages of glacial foreland succession form loose clumps or grow individually. Individual and young plants are most likely to be found in early successional stages. Seed production plays an important role in the succession process since most of the species observed on the studied foreland have a high germination capacity (Cooper et al., 2004). The seed bank in the soil on glacier forelands is many times smaller than in mature tundra communities of Svalbard (Cooper et al., 2004). However, the effective colonization of glacier forelands by seedlings germinating from the seed bank is possible. A cascade effect is also possible, when germination takes place faster in places overgrown with vegetation than in areas lacking plant cover, as observed in the glacier forelands in the central Alps (Erschbamer et al., 2008). Production of runners is another strategy that allows colonization. The species which are dominant in forelands mostly reproduce vegetatively, as observed in the Arctic and the Alps

Fig. 5 *Saxifraga cespitosa* growing between rocks in the Rieperbreen foreland. © P. Wietrzyk-Pelka.

(Stöcklin and Bäumler, 1996; Wietrzyk et al., 2016). Additional strategies that facilitate succession include pseudoviviparous reproduction, a condition in which vegetative propagules replace some or all of the normal sexual flowers in the flower heads. Vascular plant colonization is also related to the availability of propagules of fungi that form mycorrhizal associations which may be vital for successful vascular plant establishment in glacier forelands (Trappe and Luoma, 1992; Cázares et al., 2005).

A Case Study—Primary Succession in Glacier Forelands of the Svalbard Archipelago

Study Area

In Svalbard, where almost 60% of the area is glaciated (Jónsdóttir, 2005), a progressive recession of glaciers has been observed since the termination of the Little Ice Age at the end of 19th century (Błaszczuk et al., 2009). Glaciers have been reduced both in their thickness and areal extent. Measurements from north-western Spitsbergen (Moreau et al., 2005) and south of the island (Ziaja et al., 2011), indicate the intensification of glacial recession from the 1980s onwards. Glacial volume has decreased, especially in western Svalbard (James et al., 2012; Nuth et al., 2013), as exemplified by the following results from primary succession process studies conducted in the forelands of four glaciers (Fig. 6).

Longyearbreen

Longyearbreen, located in Nordenskiöld Land in central Spitsbergen, is a rather small valley glacier, which flows northeast from the accumulation zone located at c. 1000 m a.s.l. and ends at c. 250 m a.s.l. (Hagen et al., 1993). The glacier covers an area of 2.52 km², and is 3.6 km in length with a mean width of c. 500 m and an average ice depth of 53 m (Etzelmüller et al., 2000; Langford et al., 2014). Due to its location near Longyearbyen, the main settlement in Svalbard, the glacier and its foreland are frequently visited by tourists. In recent decades, when a coal mine operated on the eastern slope of the glacier valley, the intensity of human and vehicular traffic was high. Currently, there is a popular hiking route running through the glacier and its moraine (Fig. 7).

Rieperbreen

Rieperbreen, also located in Nordenskiöld Land, is a valley-confined glacier connected to the Foxfonna glacier complex; it is c. 2 km in length and less than 400 m wide, the elevation of its outlet varying from 200 to 500 m a.s.l. (Lyså and Lønne, 2001).

Fig. 6 Map of the locations of glacier forelands in Svalbard. © Norwegian Polar Institute 2018.

Fig. 7 Longyearbreen glacier and its foreland in 2018. © M.H. Węgrzyn.

In comparison with Longyearbreen, the glacier is much less often visited by tourists because of its location at the end of Bolterdalen valley (c. 14 km from Longyearbreen) (Fig. 8).

Irenebreen

Irenebreen, located in Oscar II Land, NW Spitsbergen, is one of seven glaciers surrounding the Kaffiøyra Plain. It is a valley glacier c. 4 km in length and between 1 and 1.5 km in width, bordered by Gråfjellet in the north, and by Prinsesserygen in the south, Prins Heinrichfjella in the east (Sobota, 2011). This glacier covers a total area of c. 4.1 km², the elevation of its outlet varying from c. 150 to 600 m a.s.l. (Fig. 9; Sobota, 2011).

Gåsbreen

Gåsbreen is located in the north-western part of the Sørkapp Land, on the southern shore of Hornsund (south Spitsbergen). It is a medium-sized valley glacier (c. 7.3 km in length, 14.3 km² and with a volume of 1.6 km³ in the 1990s) (Figs. 10 and 11; Hagen et al., 1993).

Methodological Approach

Fieldwork was carried out in the summers of 2008, 2011, 2012, and 2015 in the moraines of Gåsbreen, Longyearbreen, Irenebreen and Rieperbreen, respectively. One linear transect, consisting of 1 m² plots, was designated across each of the studied

forelands from the front of the glacier to the end of the foreland. Percentage cover of each vascular plant, bryophyte and lichen species was recorded from every plot with the aid of a frame measuring 1×1 m divided into 100 squares (each of 10×10 cm) (Fig. 12).

Vegetation Development and Order of Species Colonization

Similar habitat conditions prevailing on glacier forelands appear to contribute to a similar composition of species communities, as well as similar trends in the development of plant cover. However, based on studied glacier forelands, differences in the colonization process are noticeable. Within the recorded species, a group of early, intermediate and late colonizers can also be identified, among which the differences between the forelands are also visible (Table 1; Figs. 13 and 14). The four studied forelands

Table 1 Types of plant colonizers

	Type of colonizer	Gåsbreen	Longyearbreen
1. Early colonizers—species appeared first on the exposed substrate in the first stage of primary succession	1.a. Vascular plants appearing in the first succession stage and disappearing in the later stages	<i>Carex lachenalii</i> , <i>Cochlearia groenlandica</i>	–
	1.b. Vascular plants appearing in the first stage of succession, which, although not disappeared in subsequent stages, reached the maximum occurrence early on the transect	<i>Saxifraga cespitosa</i> , <i>Saxifraga cernua</i> , <i>Sagina nivalis</i> , <i>Poa alpina</i> var. <i>vivipara</i> , <i>Cerastium regelli</i>	<i>Cerastium arcticum</i> , <i>Papaver dahlianum</i> , <i>Saxifraga cernua</i> , <i>Oxyria dygina</i>
	1.c. Bryophytes appearing in the first succession stage and decreasing their number in the later stages	<i>Bryum pseudotriquetrum</i> , <i>Brachythecium turgidum</i>	<i>Bryum pseudotriquetrum</i> , <i>Brachythecium turgidum</i>
	1.d. Species present in the most of the transect, appeared in the first stage of succession, but reached the maximum occurrence in the final stage of succession	<i>Saxifraga oppositifolia</i> , <i>Cerastium arcticum</i>	<i>Saxifraga oppositifolia</i> , <i>Cerastium arcticum</i>
2. “Intermediate” group—plants that appeared for the first time in the second stage of primary succession		<i>Draba</i> sp., <i>Salix polaris</i>	<i>Draba</i> sp. <i>Salix polaris</i> , <i>Saxifraga cespitosa</i> , <i>Bryum calophyllum</i> , <i>Pohlia drummondii</i> , epilithic lichens
3. Late colonizers—species which appeared for the first time at a considerable distance from the beginning of the transect in the third or fourth stage of succession		<i>Puccinellia vahliana</i> , <i>Micranthes nivalis</i> , <i>Silene acaulis</i> , all lichens	<i>Porpidia tuberculosa</i> , <i>Pseudephebe pubescens</i> , <i>Rhizocarpon grande</i> , <i>Umbilicaria</i> sp., <i>Cetraria</i> sp., <i>Collema</i> sp., <i>Cladonia</i> sp., <i>Flavocetraria</i> sp., <i>Ochrolechia</i> sp., <i>Stereocaulon</i> sp.

Examples of species were identified along the forelands of Gåsbreen (Wietrzyk et al. 2016) and Longyearbreen.

Fig. 13 *Papaver dahlianum*, an example of an early colonizer. © P. Wietrzyk-Pelka.

Fig. 14 *Salix polaris* growing in the foreland of Rieperbreen. © P. Wietrzyk-Pelka.

showed differences in the number of species of particular plant groups and in the order of species appearance, as well as in the composition of the initial communities.

Within the Gåsbreen marginal zone, 17 vascular plant, 13 bryophyte and 18 lichen species were recorded. Vascular plants that appeared as the first on the designated transect were dominant. In the Longyearbreen foreland, 21 vascular plant, 13 bryophyte and 45 lichen species were recorded (Wietrzyk et al., 2016). The general schemes of appearance order of particular groups of organisms on Gåsbreen and Longyearbreen forelands were similar. The vascular plants were the earliest colonizers on both transects, and concurrently or shortly thereafter, the first bryophytes appeared, followed by the epilithic lichens. *Saxifraga oppositifolia* (Fig. 17) proved to be dominant on both forelands, and *Cerastium arcticum* was frequently recorded. Vascular plants were mostly found in areas with a moderate slope, avoiding both the most exposed slopes and wetlands in lower areas. They also occupied surfaces between large blocks of rock, but the majority of bryophytes occurred in wet places, and on the fine grained substrate between stones. Epilithic lichens were observed on large stone blocks and smaller stones, even in steeply sloping areas. The Longyearbreen foreland was dominated by lichens, mostly epilithic. The low number of epigeic lichens and vascular plants seems to be caused mainly by human trampling on the foreland as a result of a significant increase in tourism, which has expanded along Longyearbyen (Kaltenborn, 2000). Such trampling greatly inhibits or even prevents the development of terrestrial lichens (Wietrzyk et al., 2017). Regarding Irenebreen and Rieperbreen forelands, cryptogams were the most numerous group: 113 lichen species and 49 bryophyte species, while vascular plants comprised only 29 species. In both moraines, bryophytes were the first to colonize the freshly deglaciated areas. For all recorded taxa, lichens were the dominant group, with 88 species recorded for the Rieperbreen moraines and 60 species for the Irenebreen foreland. For bryophytes, 37 and 19 species were noted in Rieperbreen moraines and Irenebreen foreland, respectively. Vascular plants were the least numerous, with 21 species recorded in the Rieperbreen foreland and 20 species recorded in the Irenebreen foreland. Figs. 15 and 16 show the development of lichen, bryophyte and vascular plant cover and first appearance of each species along the forelands of Irenebreen and Rieperbreen.

The order of entry of particular groups in the studied foreland and other glacier moraines of Svalbard seem to be similar. Bryophytes or vascular plants appear first, while epigeic lichens enter later, when the substrate is more stable (Moreau et al., 2005, 2008). The most abundant species of vascular plants are *Saxifraga oppositifolia* and *Cerastium arcticum*, but *Sagina nivalis* and *Saxifraga cespitosa* are also often recorded in glacier forelands. *S. oppositifolia* was the dominant species in deglaciated areas in both the north (Hodkinson et al., 2003; Moreau et al., 2005) and the south of Svalbard (Pirożnikow and Górniak, 1992; Wojtuś et al., 2008). *Cerastium arcticum*, together with *Cochlearia groenlandica*, *Sagina nivalis*, and *Saxifraga cespitosa* were usually recorded in the younger parts of the Midtre Lovénbreen and Werenskiöldbreen marginal zone (Moreau et al., 2008). The same trend was observed in the Longyearbreen and Gåsbreen forelands, but *Sagina nivalis* was recorded rather in the older fragments of the Irenebreen, Rieperbreen and Werenskiöldbreen forelands (Wojtuś et al., 2008; Wietrzyk et al., 2018).

Among all taxa forming Arctic vegetation, cryptogamic species seem to be the principal components. Their participation in the formation of plant communities as a result of the primary succession process in freshly deglaciated areas of glacier forelands is significant. The rapid enlargement of ice-free areas within marginal zones of Arctic glaciers provides new habitats for possible

Fig. 15 Development of vegetation cover and species appearance during primary succession in the Irenebreen foreland.

colonization by organisms. These areas are firstly inhabited by cryptogams, such as cyanobacteria, mosses, liverworts and lichens, due to their strong pioneering abilities which allow them to survive in the extremely harsh environments of glacier forelands. In the case of lichens, epilithic taxa may also occur close to the glacier forehead since they colonize stable rocks uncovered by the retreating ice (Fig. 18). Epigeic lichens usually inhabit more mature parts of the foreland, where ice had disappeared earlier, and species have had sufficient time to colonize the substrate, and where the influence of dead-ice thawing and glacier-affected microclimate is reduced (Wietrzyk et al., 2018). For all glacier forelands in Svalbard, epigeic lichens appeared in the older parts of the moraine (Moreau et al., 2009; Wietrzyk et al., 2016, 2018). Apart from common *Collema* species, such as *C. ceraniscum*, species from the genus *Stereocaulon* (Fig. 19) were frequently recorded (Moreau et al., 2009; Wojtuń et al., 2008; Wietrzyk et al., 2016, 2018). These species, apart from *Chlorophyta* photobiont, also contain cyanobacterial symbionts which bind atmospheric nitrogen, influencing the colonization potential of these lichens. These probably play an important role in the soil-forming processes (Sancho et al., 2011). In the studies conducted in Werenskioldbreen, Tishkov (1986) emphasized the importance of so-called micro-depressions, which allow a faster process of primary succession, because of an optimal condition regarding the snow accumulation and moisture contents. Compared to lichens, bryophytes, especially minerotrophic species, inhabit moist areas that dominate the younger parts of the foreland and seem to tolerate the erosional activity of proglacial rivers that form periodically near the glacier forehead (Walker et al., 2001; Atherton et al., 2010; Wietrzyk et al., 2018). It should be noted that the number of cryptogamic species colonizing freshly deglaciated forelands exceeds the number of vascular plants species (Wietrzyk et al., 2016, 2017). Consequently, the glacier forelands seem to offer habitat conditions where cryptogams are less vulnerable and less exposed to competition from vascular plants, compared to tundra communities with better-developed vascular plant cover (Alatalo et al., 2017). As regards climate warming, glacier melting and the phenomenon of Arctic greening, glacier forelands may serve as cryptogam refugia in future, where such species will be able to withstand competition from vascular plants.

Environmental Factors Influencing Life Around Arctic Glaciers

Clements (1916, 1928) indicated that the following processes drive succession: denudation, migration, establishment, competition, reaction, and stabilization. Within these, denudation plays a vital role, since this process of disturbance creates a barren substrate largely devoid of biota (Walker and del Moral, 2003). Due to the relationship between primary succession and geomorphological processes, the moraine's vegetation does not develop in the climax communities but only reaches the near-climax communities. Initial communities developing in the forelands are often disturbed by environmental factors. It is believed that river runoff is one of

Fig. 19 *Stereocaulon alpinum* growing in the foreland of Rieperbreen. © P. Wietrzyk-Pelka.

the most influential process in the formation of lowlands and slopes in the glacier moraines and therefore has an important impact on vegetation development. Within strongly eroded regions, younger succession stages were observed than in the same aged parts of the foreland without flooding (Moreau et al., 2008). Wojtuń et al. (2008) also drew attention to the relationship between the type of substrate and the occurrence of particular groups of plants, while Kuc (1996) emphasized lichen preference for a stable substrate. Research conducted in Gåsbreen foreland (Wietrzyk et al., 2016) showed that the distance from the front of the glacier was the main factor influencing the distribution and abundance of vegetation; also, the fine grain material and slope steepness had a great importance. Studies by Wietrzyk et al. (2018) in the Irenebreen foreland demonstrated that apart from soil pH, distance from the glacier forehead and total nitrogen content also affects species occurrence and vegetation development. The greater percentage cover of vascular plants and terrestrial lichens in the older part of a moraine was associated with a lesser impact of glacier microclimate due to greater distance to the glacier forehead, as well as more stable substrate unaffected by glacial rivers and ice-cores (Fig. 20). The stable substrate allows more time for plant colonization; in contrast, poorer vegetation, mainly composed of bryophytes and algae, occur in wet and unstable places, periodically eroded by glacial rivers.

Abstract

Pollution, ocean acidification and global warming are all major threats to Arctic ecosystems and are all inextricably linked. Major global air and ocean currents bring pollutants north to the “Arctic sink” where they accumulate over time, affecting ecosystems and wildlife. Meanwhile, carbon pollution from fossil fuels is causing widespread ocean acidification and global warming, which is happening two to three times faster in the Arctic than other regions. While climate change is having direct effects on Arctic ecosystems, the dynamics of pollutants within Arctic ecosystems are also being affected, enhancing pollutant mobility and effects in some cases.

Contaminants

Contaminants travel to the Arctic from more industrialized southern areas through the atmosphere (days/weeks), rivers (weeks/years) or the ocean (years). Because of the cold climate in the Arctic, and the nature of the contaminants, they tend to persist in this environment, cycling among abiotic matrices (air, water, snow, sediment) and making their way into the food web (Fig. 1). Many of these compounds bioaccumulate (build up in an animal over its lifetime) and/or biomagnify (concentrate up the food chain so that top predators have the highest levels). Long-term and/or high-level exposure to contaminants can lead to serious health effects in wildlife and people. Contaminants of concern in the Arctic include mercury, radioactivity, plastics and a broad range of persistent organic pollutants, which, for the most part, are man-made carbon-based compounds. All these contaminants are of concern because they are persistent in the environment and toxic.

Mercury

Mercury is a naturally occurring element that, since industrialization, has been emitted to the atmosphere through coal combustion; more recently, artisanal and small-scale gold mining has become an additional major source. The total amount of mercury released to the air each year from anthropogenic sources is estimated to be about 2000 tonnes each year. A further 3000–4000 tonnes are released to the air either from natural sources, or as a result of re-emission of mercury that has previously been deposited onto surfaces, back into the air. It has been estimated that Arctic Ocean seawater currently accumulates about 25 tonnes of mercury each year (AMAP, 2011). Mercury tends to accumulate in muscle and liver tissue of vertebrates and can have toxic effects on the nervous, digestive and immune systems, particularly in the unborn fetus. Mercury is considered by the World Health Organization as one of the top 10 chemicals of major public health concern (WHO, 2017).

Mercury is mostly deposited from the air in inorganic forms which are not very bioavailable. However, bacteria can methylate these forms, creating methylmercury, a toxic organic form that is readily bioavailable, bioaccumulates within animals (and people) and biomagnifies up the food chain. Methylation can occur in aquatic environments, sediments and wetlands. Virtually all the mercury present in fish is in the toxic methylmercury form, allowing biomagnification through the Arctic marine food chain to seals and fish-eating seabirds, and on to polar bears (*Ursus maritimus*) and people. As a result, mercury levels tend to be higher in marine as compared with terrestrial ecosystems. In contrast, in the terrestrial system, mercury (mostly the less toxic inorganic forms) accumulates in caribou and reindeer (*Rangifer tarandus*) liver and kidneys from lichens, the primary winter forage. Lichens have no roots, just anchors, and effectively absorb their nutrients (and contaminants) from the atmosphere. Other terrestrial ungulates, such as moose (*Alces alces*) and muskox (*Ovibos moschatus*), have much lower levels of mercury since they do not normally consume lichens and their diet of browse and grasses contains little mercury.

Mercury levels in the Arctic are now three times higher in freshwater and 10 times higher in marine ecosystems than they were in the early 1800s. Over the past 150 years, there has been a 10-fold increase in mercury levels in upper trophic level marine animals (beluga, ringed seal, polar bear, birds of prey); over 90% of that increase is believed to be anthropogenic in origin (AMAP, 2011). Accumulation of mercury varies geographically within the Arctic, with levels being higher in beluga (*Delphinapterus leucas*), ringed

Fig. 1 The Arctic marine food web (AMAP, 2012).

seals (*Pusa hispida*) and polar bears from the Beaufort Sea as compared with other Arctic regions. This is likely due to habitat use and food web structure. Latitudinal trends have also been observed for ringed seals and seabirds, with greater concentrations in the High Arctic than at sub-Arctic sites (AMAP, 2011). Research is continuing to try to identify underlying processes leading to temporal and geographic variability in mercury levels in Arctic wildlife.

Although most terrestrial and marine mammals are at low risk of toxicological effects from mercury exposure, for some species at high marine trophic levels, such as polar bear, pilot whale (*Globicephala melas*), narwhal (*Monodon Monoceros*), beluga and hooded seal (*Cystophora cristata*), a proportion of the population is at high or severe risk (AMAP, 2018a). Measured biological effects in these species include inhibition of brain neurochemical receptors and immune suppression. Mercury concentrations in Arctic birds were above toxicity benchmarks in many areas of the marine environment, particularly for seabirds. Some bird species have mercury levels in their eggs sufficiently high to raise concern about negative effects on reproductive success. New research focusing on the effects of mercury exposure on gene expression holds promise for increasing our understanding of subtle toxicological effects (AMAP, 2011).

Toxicological effects of mercury in the Arctic are not limited to wildlife. Although blood mercury levels in residents of Nunavik have declined since the early 1990s, in 2013, 44% of Inuit women from Nunavut still had levels that exceeded health guidelines and nearly 60% of preschool children in Nunavut exceeded the provisional tolerable weekly intake level for methylmercury set by the World Health Organization (Tian et al., 2011). Although it is promising that levels are declining, we know from wildlife research that this is not due to declining mercury concentrations in traditional food (Arctic wildlife), but more likely from a decline in traditional food consumption. In addition, a long-term study on the effects of mercury from prenatal exposure in Nunavik found developmental effects including lower estimated IQ, poorer comprehension, perceptual reasoning, memory and early processing of visual information, and increased risk of attention problems and ADHD behavior (CACAR, 2017). This is still clearly a health issue for Arctic people, particularly those relying on the marine environment for subsistence food.

Concern over high mercury levels in the environment led the United Nations Environmental Program to create the Minamata Convention on Mercury, a global treaty to protect human health and the environment from the adverse effects of mercury. The Convention came into force in 2017 and bans or limits mercury mining, uses, emissions to air and releases to land and water

(UNEP, 2018a). Although it is too early to see the effects of the Convention in environmental mercury concentrations, it is an encouraging step.

Radioactivity

Radionuclides occur naturally in the environment as radioactive minerals and cosmic radiation from outer space. They are also produced by medicine and industry, and may result from accidents in nuclear facilities and nuclear bomb explosions. Radon is a naturally occurring radioactive gas and the second leading cause of lung cancer after tobacco smoking. It can be increased by industrial activities such as mining and fracking, often due to dumped waste products. Nuclear testing in the Pacific, Russia and elsewhere (1945–95) resulted in global fallout of radionuclides throughout the Northern Hemisphere, including the Arctic (UNSCEAR, 2000). Meanwhile, regular dumping of liquid and solid radioactive waste in the Arctic was practiced by the former Soviet Union and later by Russia from the early 1960s until the early 1990s. Dumping of radioactive waste was also carried out by other countries in the Atlantic and Pacific oceans despite strict international guidelines to the contrary (Sivintsev et al., 2005). The Arctic Ocean has received additional inputs of radioactivity from the 1989 sinking of a Russian nuclear submarine containing a nuclear reactor and two nuclear-warhead torpedoes (Gladkov et al., 1994), discharges from nuclear fuel reprocessing plants at Sellafield, United Kingdom and Cap de la Hague (AMAP, 2010) and the nuclear power plant accidents at Chernobyl in 1986 and Fukushima Daiichi in 2011. Radionuclides accumulate in the muscle tissue of animals and people. Exposure to low-levels of radiation does not cause immediate health effects, but can increase the risk of cancer over a lifetime.

In the terrestrial ecosystem, cesium-137 can readily accumulate in lichens, a major food source for Arctic caribou and reindeer. This radionuclide can be released into the environment from nuclear facility accidents and nuclear bomb explosions. In Arctic Canada, cesium-137 continues to decline in caribou from the original input from nuclear testing in the 1960s and did not increase as a result of the Chernobyl or Fukushima accidents (Macdonald et al., 2007; Stocki et al., 2016). However, cesium-137 did increase in reindeer in Scandinavia as a result of atmospheric fallout from the Chernobyl accident. Levels have been decreasing since that time, but since the early 2000s there has been a slower decline, indicating that radioactive contamination is being maintained in the system, bound in the soil. This was confirmed by a sudden rise in cesium-137 in reindeer from southern Norway in 2014, caused by an unusually large number of mushrooms on their feeding grounds, some of which are known to be efficient accumulators of radioactive cesium (Skuterud and Thørring, 2012). Current levels of anthropogenic radioactivity measured in Arctic marine and freshwater environments are very low and generally declining.

Persistent Organic Pollutants (see Table 1 for Acronyms)

Persistent organic pollutants (POPs) have been used industrially (e.g., PCBs) and agriculturally (e.g., DDT) since the early 20th century and enter the environment during their production, use or disposal. New POPs, being created as household products such as stain guards, nonstick coatings and flame retardants, are finding their way from local drains and landfills into the ecosystem, and new compounds are being created constantly. Most POPs tend to accumulate in the fatty tissue of vertebrates, including the liver, and can affect immune, endocrine and reproductive function. POPs may also cause increased susceptibility to disease and damage to the nervous system.

Most POPs that have been banned for an extended period of time (>20–30 years) in developed countries are now showing slower rates of decline in Arctic air and biota, indicating that they are approaching steady state with other environmental media and secondary sources now dominate. However, some POPs are showing no declines in some areas (e.g., PBDEs in air at Alert, Canada, possibly related to influence from a nearby military site and generally much higher PBDE use in North America), while some are still increasing (e.g., HCB and PCBs in air in Svalbard and Iceland; HCB, PBDEs, PFOS, β -HCH in some wildlife populations). This may be related to revolatilization from the open ocean due to significant ice retreat or melting glaciers in recent years as a result of global warming (AMAP, 2014).

Biological effects of POPs in wildlife are challenging to quantify. Laboratory studies are the usual benchmark for ascertaining a cause-and-effect relationship between a contaminant and an effect. However, due to the sheer number of POPs in the Arctic environment, these studies are virtually incapable of duplicating an accurate field scenario. Scientists have opted to investigate biomarkers (e.g., hormones, vitamins, immune system activation, liver enzyme activity) in wildlife, as indicators of biological effects and specific effects associated with POPs have been reported in several Arctic species. Based on PCBs being the dominant effect contributor, killer whales (*Orcinus orca*) were the species most at risk, while long-finned pilot whales from the Faro Islands and several populations of birds of prey (white-tailed eagles [*Haliaeetus albicilla*], peregrine falcons [*Falco peregrinus*]) are also at risk. Genotoxicity has also been shown for polar bears and some birds and fish, mainly driven by PCB exposure (AMAP, 2018a).

Levels of certain POPs (e.g., oxychlordane, DDT) are 2- to 10-fold higher among Inuit from the eastern Canadian Arctic and Greenland as compared to other populations in the Arctic (Norway, Sweden, Iceland, western Canada). However, concentrations of many of these compounds have decreased over the last two decades, particularly in the Inuit from the eastern Canadian Arctic (AMAP, 2014). For example, levels of POPs have declined by about 80% from 1992 to 2013 in pregnant Inuit women and by about 40% in Inuit children from Nuavik, likely due to the lowering of environmental levels of these compounds (CACAR, 2017). Studies of contaminant levels in the blood of residents in northern Norway and parts of Arctic Russia show that levels of POPs and PFASs subject to international regulations or bans have been decreasing over the past three decades in local residents, while concentrations

Table 1 Chemicals of concern to the Arctic as designated under the Stockholm Convention (UNEP, 2018a), the Minamata Convention (UNEP, 2018b) and Chemicals of Emerging Arctic Concern (AMAP, 2017)

		Acronym	Chemical
Minimata Convention	Initial “Dirty Dozen” (2004)	Hg	Mercury
Stockholm Convention			Aldrin
			Chlordane
		DDT	Dichloro-diphenyl-trichloroethane
			Dieldrin
			Endrin
			Heptachlor
			Mirex
			Toxaphene
			HCB
	Added (2009)	PCBs	Polychlorinated biphenyls
		PCDD/PCDF	Polychlorinated dibenzo- <i>p</i> -dioxins/furans
		HCH	Hexachlorocyclohexane (α , β , γ)
			Chlordecone
		HBCDD	Hexabromocyclododecane
		PBDEs	Polybromodiphenyl ethers
		HBCD	Hexachlorobutadiene
		PeCB	Pentachlorobenzene
		PCP	Pentachlorophenol
		PFOS	Perfluorooctane sulfonic acid
	Proposed for listing (2018)	PCNs	Polychlorinated naphthalenes
		SCCPs	Short-chain chlorinated paraffins
			Endosulfan
			Dicofol
		PFOA	Perfluorooctanoic acid
		PFHxS	Perfluorohexane sulfonic acid
Chemicals of emerging Arctic concern		PFASs	Per- and polyfluoroalkyl substances (including PFOS, PFOA, PFHxS)
		BFRs	Brominated flame retardants (including PBDEs)
		CFRs	Chlorinated flame retardants
			Organophosphate-based flame retardants and plasticizers
		Phthalates	
	SCCPs	Short-chain chlorinated paraffins	
		Siloxanes	
	PPCPs	Pharmaceuticals and personal care products	
	PCNs	Polychlorinated naphthalenes	
	HCBd	Hexachlorobutadiene	
CUPs	Current-use pesticides		
PCP	Pentachlorophenol		
PCA	Pentachloroanisole		
		Organotins	
	PAHs	Polycyclic aromatic hydrocarbons	
		New’ unintentionally generated PCBs	
		Halogenated natural products	
		Marine plastics and microplastics	

of unregulated PFASs are still increasing (AMAP, 2017). This is an indication of the success of international regulation of the specified contaminants.

The Stockholm Convention on POPs is a global treaty created to protect human health and the environment through the reduction, restriction or elimination of the production and use of specified POPs. The Convention came into force in 2004 with a list of 12 POPs, the “Dirty Dozen” and the addition of another 16 POPs since that time (UNEP, 2018b). As a result of this initiative, concentrations of many POPs have decreased in the Arctic environment. Although new emissions of these chemicals have been virtually eliminated, large quantities remain in environmental reservoirs (oceans and forests). These POPs will eventually break down, but the some compounds (e.g., PCBs) will persist for a long time. Meanwhile, scientists continue to discover previously unknown contaminants in the Arctic; many of these newer POPs will continue to increase in the environment until they are regulated on a global basis. Table 1 provides a list of chemicals currently being regulated (or being considered for regulation) and those considered by the Arctic Monitoring and Assessment Program to be of emerging Arctic concern (AMAP, 2017).

Plastics

Plastic debris has emerged as a major environmental concern worldwide. Plastics are made from a wide range of organic polymers that are semipersistent, breaking down from larger to smaller plastic particles through exposure to ultraviolet light and physical abrasion, but this is a slow process (Gewert et al., 2015). Most marine plastics are currently in the form of microplastics (<5 mm) (Cózar et al., 2014). Plastics are released into the environment during industrial activities such as commercial fishing, use of plastic abrasives and spillage of plastic pellets, but also from domestic applications such as washing of plastic microfiber clothes, use of personal care products containing microplastics (e.g., toothpaste and exfoliators) and municipal wastewater. Another major source of plastics in the oceans is landfills in coastal cities.

Plastics affect marine organisms through entanglement and blockage of intestines (Laist, 1987), but also through toxicological effects of plastic-related chemicals (Koelmans et al., 2014). Research on microplastics and their effects in Arctic ecosystems is just beginning, but they have been discovered in Arctic sea ice (Obbard et al., 2014), sea water (Lusher et al., 2015), sediments (Bergmann et al., 2017), fish (Kühn et al., 2018) and marine birds (Travail et al., 2015). Microplastics exhibit many of the same characteristics of POPs that make them a risk to Arctic ecosystems and people.

Ocean Acidification

Arctic marine waters are experiencing widespread and rapid ocean acidification, with important physiological and geochemical thresholds already surpassed. The primary driver of this change is uptake of carbon dioxide emitted to the atmosphere by human activities, but other biogeochemical processes are also contributing. This phenomenon is intensified in the Arctic relative to other regions due to low ocean temperatures that increase gas solubility and the inflow of naturally acidic water from the Pacific Ocean, river runoff and ice melt. The degree and distribution of acidification is not uniform across the Arctic Ocean, resulting in high temporal and spatial variability. This is driven by sea-ice extent, freshwater inputs, ocean currents, water temperature and the effects of biochemical processes.

Projections indicate that acidification in the Arctic Ocean will continue, although with considerable regional variability. It is anticipated that parts of the Arctic Ocean will experience significant ecological shifts over the coming decades, with direct and indirect effects on marine life, including changes in calcification, growth, reproduction, metabolic rates and food availability and quality. Calcification of the shells of marine invertebrates is key to their survival. As Arctic waters acidify, the potential failure of marine invertebrate shell formation threatens a major component at the bottom of the marine food chain. These effects are likely to be variable, depending on the ability of each species to adapt to the changing environment. Changes in fish and marine mammal populations may ultimately pose risks to commercial, subsistence and recreational fisheries and hunting (AMAP, 2018b).

Global Warming

Warming is occurring faster and with greater magnitude (two to three times higher) in the Arctic as compared with other regions mainly because of feedback mechanisms associated with less snow and ice now in this region. As a result, the Arctic is one of the regions at disproportionately higher risk from global warming (IPCC, 2018). Higher average temperatures in the Arctic will cause a reduction in glaciers, sea ice and permafrost, and will result in some shifts in habitat as more southern species gradually move north (this includes plant as well as animal species). Increasing temperatures will also affect the movement of contaminants around the globe, including movement into the Arctic. More intense, frequent and unpredictable extreme weather events are predicted for the all regions, including the Arctic.

Sea ice is expected to diminish, both in terms of cover and thickness. This will affect wildlife that use sea ice for feeding and habitat (Arctic cod [*Boreogadus saida*], seals, walrus (*Odobenus rosmarus*) and polar bears) and may cause shifts in feeding ecology and habitat use. The melting of the sea ice itself (along with melting glaciers) will increase sea level, changing ecosystems as some rivers disappear. Melting ice may in turn release contaminants stored in the ice, including mercury, POPs and microplastics (Obbard et al., 2014). It will also provide increased access and resulting opportunities for shipping and resource extraction in the Arctic, inherently increasing risks associated with habitat loss and fragmentation, wildlife disturbance, increased fishing harvest and pollution. A bigger risk is related to potential accidents, both in the Arctic Ocean and on the land, which could introduce significant sources of pollution to the environment but are particularly difficult to predict.

Melting permafrost in the Arctic will increase erosion and create instability for infrastructure (housing, municipal services, coastal structures), with implications for health, safety and well-being as well as economic considerations. Permafrost soils store nearly twice as much mercury as all other soils, the ocean and the atmosphere combined, and it is estimated that 793 Gg (793 million kg) of mercury could be released to the environment from permafrost thawing over the next century (Schuster et al., 2018). This could have major health implications for the freshwater and marine environments as well as humans using wildlife as subsistence food sources.

Increasing temperatures will affect how contaminants move around the planet. Atmospheric models show that higher temperatures due to global warming will enhance volatilization and re-emission of POPs and mercury from soils, water bodies and ice to air, increasing their atmospheric transport to the Arctic. However, this impact may be offset for some POPs by increased degradation

due to increased temperatures and by decreasing emissions. Overall, model studies of POPs do not show clear agreement on whether climate changes will reduce or increase concentrations of POPs in the Arctic; chemical responses will depend on the properties of each group of POPs (AMAP, 2014). In addition to enhanced volatilization, the biogeochemical cycling of mercury is likely to be affected by increased methylation of inorganic mercury due to increased algal growth in lakes. The most significant increase in radiation exposure to Arctic residents may arise from enhanced release of radon-222 from soil due to thawing of permafrost and decreased snow cover (with a resulting increase in environmental levels of lead-210 and polonium-210) (AMAP, 2010). New potential sources of radioactivity to the Arctic include the planned decommissioning of nuclear power plants which may lead to temporary increases in radioactive discharges that could eventually reach the Arctic. New power plants are also planned in areas distant from the Arctic and many older plants have been granted extensions to their operating licenses; accidents such as those at the Chernobyl and Fukushima Daiichi nuclear facilities have demonstrated that even accidents far from the Arctic have the potential to affect the Arctic region. The waste streams produced in the extraction of hydrocarbons and minerals—including uranium mining—contain naturally-occurring radioactive substances found in bedrock and will likely lead to enhanced releases and mobilization of naturally-occurring and technologically-enhanced naturally occurring radioactive material to the environment (AMAP, 2010). There may also be redistribution of mercury and radionuclides from natural events such as forest fires, that are expected to increase in frequency and intensity with global warming.

Encroachment of southern species into the home ranges of Arctic populations may result in changes in wildlife health from a number of perspectives: potential habitat loss and/or fragmentation, changes in migration routes, food web structures, feeding habits and diet, parasite loads, incidence of disease, and potential new introduced parasites and diseases. Increased human exploitation of Arctic resources will also likely result in loss of habitat, increased disturbance and an increase in local pollution, including plastics. These factors, along with the increase in extreme weather events, will cause increased cumulative stress in many Arctic wildlife populations, which can in turn, enhance the sensitivity of some species to certain pollutants.

On a human level, fishing, hunting and gathering activities are key parts of the northern economy and an important way of life for Arctic indigenous people. These activities will be strongly affected by unpredictable extreme weather events and the availability and health of wildlife species being directly affected by global warming and pollutants.

Abstract

This chapter describes the general climates of Greenland, and summarizes the main driving factors.

Introduction

Greenland is the largest island in the world, covering approximately 2.17 million square kilometers. The majority of the island is covered with ice bodies of which the Greenland Ice Sheet (GrIS) is by far the largest, covering about 80% of the island. A minor part, around 420,000 km², is ice-free land, and home for the terrestrial ecosystem. The island is surrounded by the North Atlantic Ocean to the southeast, the Greenland Sea and the Arctic Ocean to the northeast and north, respectively, and separated from Canada by Baffin Bay to the north and the Labrador Sea further south. The interplay between these waters, the GrIS, incoming radiation, and lastly the wind systems that pass or form over Greenland, determines the general climate on the island.

Ocean Currents and Sea Ice Around Greenland

From a global perspective, the most critical ocean current in the waters around Greenland is the North Atlantic Current, which maintains heat transport through the ocean around southeast Greenland ([Fig. 1](#)). The thermal difference in sea temperatures, occurring from differences in solar heating between low and high latitudes, combined with a haline forcing in the North Atlantic, drives a northward flow of warm surface water, and a southward flow of cold deep water. This thermohaline circulation is part of the Atlantic meridional overturning circulation (AMOC), which is a system of ocean currents in the North Atlantic, including the aforementioned North Atlantic Current. In its current state, the northward flow of relatively warmer surface water and the linked evaporation bring warmth and precipitation to southern Greenland. Climatic warming may trigger a weakening of the AMOC, resulting from less formation of cold and haline sinking water. From modeling studies, it has been suggested that a marked weakening of the thermohaline process within AMOC could decrease temperatures in southern Greenland by 6–10°C ([Stouffer et al., 2006](#)) and decrease precipitation by 0–0.3 m year^{−1} within 20–30 years after a shutdown ([Vellinga and Wood, 2002](#)). Such model results have an inherent uncertainty. However, current observations of sea surface temperatures show a local cooling anomaly southeast of Greenland over the past century, and a recent study attributes this to a 15% weakening of the AMOC since the mid-20th century ([Caesar et al., 2018](#)).

At a smaller scale than the AMOC and North Atlantic Current, two ocean currents of importance for the Greenlandic climates are the east and west Greenland Currents. The East Greenland Current originates in the Arctic Ocean, and begins with a southward flow through Fram Strait, along the continental shelf on the east coast of Greenland ([Fig. 1](#)). The temperature of the surface water is generally below 0°C, but it can reach 3–5°C in the summer ([Buch, 2001](#)). The current flows to the southern

Fig. 1 Four prominent ocean currents with relevance for Greenland's Climates. NAC = North Atlantic Current; WGC = West Greenland Current; EGC = East Greenland Current; IC = Irminger Current.

tip of Greenland, Nunap Isua/Cape Farewell, and then curves back northward along the west coast of Greenland, eventually becoming the West Greenland Current. The West Greenland Current transports this now cold (below -1°C ; Cuny et al., 2002) water northward, parallel to the coastline of western Greenland. Icebergs are carried by the current towards $60\text{--}70^{\circ}\text{N}$, after which the current turns west and transports larger icebergs away from the coast and into Baffin Bay at $70\text{--}75^{\circ}\text{N}$. At these northern latitudes, the West Greenland Current meets with waters from the Canadian Arctic, forming the southward Baffin Current (Melling et al., 2001). Another current, the Irminger Current, originates from convection in the Irminger Sea southeast of Greenland, where a mixture of Atlantic and local low-salinity water moves from east to west Greenland (Fig. 1). It meets the warmer Subatlantic waters (can be above 5°C during the winter), which originate from a branch of the thermohaline North Atlantic Circulation. Together, they result in warmer winter conditions as well as high precipitation levels year-round in the coastal areas of south Greenland.

The East Greenland Current transports sea ice from the Arctic Ocean and southward along the Greenlandic east coast. This sea ice, named "Storis," is formed at high northern latitudes. It is consequently perennial in origin and in most cases about 3 m thick during winter, resulting in an estimated average annual ice flux of approx. $2200\text{ km}^3\text{ year}^{-1}$ (Kwok et al., 2004). The Storis covers the ocean near the east coast of Greenland most of the year, and has its greatest extent in February and March. The minimum extent occurs in August and September with a southern boundary of the sea ice around 75°N . The other type of sea ice with importance for Greenland climates is the West ice, which forms in Baffin Bay and Davis Strait during winter. It reaches its maximum extent around March, with a thickness of approx. One meter (Buch, 2001). It builds up from the north, and reaches Northwest Greenland in October, where after it expands southward. The southernmost border has moved northward during recent decades. During particularly warm winters this boundary can be found around Disko Bay (Fig. 2). This sea-ice decline has been reported to influence the general climate on the west coast, including plant growth in the region (Hollesen et al., 2015). The West ice never reaches southernmost Greenland due to the inflow of relatively warmer Irminger water and Subatlantic water during winter. Rapid disintegration of the West ice does not start before May, and the West ice is fully melted by late summer (Fig. 2).

Fig. 2 Sea ice distribution in 2018 at its maximum (mid-March) and minimum (September) extent, as observed by satellite. This year can be compared to the median ice edge (1981–2010) to illustrate the low extent of sea ice, particularly in September. Atmospheric Circulation and Wind Patterns

Regional Circulation and Wind Patterns

There are three air masses that are essential to the climate of Greenland: the Tropical-, the Polar-, and the Arctic air masses (Hansen, 2001). The Tropical air masses originate from high-pressure systems in the subtropics. Part of these air masses are formed over the Atlantic Ocean in the region between Bermuda and the Azores. Consequently, these are marine, meaning warm and moist, particularly in their lower layers. The Polar air masses influencing the Greenland climates originate from continental northern Siberia and Canada, whereas the colder Arctic air masses form over the Polar Sea and Arctic basin. Both the continental Polar and Arctic air masses are primarily formed over snow- and ice-covered surfaces, and are consequently dry and cold.

The boundary where the Tropical air masses meet the Polar and Arctic air is known as the Polar front, whereas the Polar and Arctic air masses meet at the Arctic front. When irregularities arise along the Polar front, a wave of unstable air is formed which leads to cyclogenesis, that is, they turn into low pressure systems (see a cyclone example in southeast Greenland on Fig. 3A). Eventually, the low pressure systems take on a cyclonic motion, often traveling from west to east. If formed west of Greenland, these traveling cyclones will be deflected by Greenland, in particular the GrIS, and will then continue to travel parallel to the coast. Their embedded frontal systems cause unstable weather in the areas over which they pass. The location of the Polar front is most variable during summer, but is generally positioned over Greenland's latitudes (Hansen, 2001). The cyclones formed west of Greenland rarely travel across the high GrIS. Rather they travel northward along the west coast, until they dissolve over the sea between Canada and Greenland. During winter, the colder northern air masses usually drive the Polar front south of Greenland, and the low-pressure areas pass over the southern parts of the island, or travel northward in the Denmark strait between Greenland and Iceland. In periods unaffected by low pressure systems, it is common for Greenland to experience inversions of the thermal lapse rate (see section **Temperature and Precipitation and Terrestrial Ecosystems**). This causes stable and very calm conditions, which prevail 20%–30% of the time, particularly on the east coast (Hansen, 2001) which is less affected by the low-pressure systems from the West, according to meteorological observations from the Danish Meteorological Institute (DMI).

Fig. 3 Wind at the surface pressure level. (A) Shows a low pressure system in southwest Greenland in the Tasiilaq area. This low pressure system has wind speeds up to 25 m s^{-1} , and is strong enough to blow across the southern part of the Greenland Ice Sheet (GrIS). In typical situations, the winds are deflected by the high elevations of the GrIS. The low pressure system also breaks up the katabatic winds in the southern part of Greenland. (B) Depicts a typical calm day with katabatic winds around $6\text{--}8 \text{ m s}^{-1}$, and with the distinct canalizing wind stream from the GrIS and southeast-ward across Tasiilaq. Source: earth.nullschool.net and NCEP.

Circulation and Wind Patterns Related to the Greenland Ice Sheet

The GrIS has a negative net radiation balance due to the high albedo snow- and ice-covered surface reflecting the majority of the incoming radiation away from the surface of the Earth. This causes a cooling of the air masses above the GrIS and forms a relatively stable thermal high-pressure system year-round. At the surface, the wind direction across the GrIS is generally affected by the pressure gradient between this high pressure and a lower pressure over the coastal zone and beyond. The higher density of the cold air masses formed over the GrIS causes air to sink towards the coasts under gravitational influence in all directions away from the GrIS. These descending winds are known as katabatic winds, and their speed varies on a local scale depending on slope and pressure gradient, although they are often around $6\text{--}8 \text{ m s}^{-1}$. The katabatic winds are more prevalent during winter and better developed on clear days with low temperatures over the GrIS (Przybylak et al., 2003). This advecting dry air generally affects the adjacent ice-free landmasses along the margin of the ice-sheet. It shields the ice-free land from precipitation systems originating from the ocean. An example is shown on Fig. 3A and B where katabatic winds descend from the GrIS and out towards the coasts.

Local Wind Patterns

Locally, the wind patterns are controlled by the topography, ice caps, and proximity to larger water bodies. One example of this topographic control occurs around the Kangerlussuaq fjord on the east coast, where the topography shelters the land from strong katabatic winds (Sechrist et al., 1989) (not to be confused with the more commonly known settlement Kangerlussuaq on the west coast). Other areas are exposed to very strong katabatic winds through a canalizing effect (Cappelen et al., 2001). The latter situation is depicted on Fig. 3B, showing the canalizing effect of katabatic winds around Tasiilaq in east Greenland. A peculiar phenomenon related to the katabatic winds is the so-called Piteraqa, which is a combination of ambient katabatic winds combined with a sudden and fast drainage of cold air otherwise stored at a topographic plateau at higher elevations. Wind speeds of more than $70\text{--}80 \text{ m s}^{-1}$ (up to 288 km per hour) have been recorded during a Piteraqa, thus living up to its name “that which attacks you.”

Also other local wind patterns are directly related to the topography, oftentimes with a diurnal or seasonal cycle. Valley wind systems develop in many areas: Surface heating early in the day results in upward moving air masses along the mountain slopes, and subsequently the wind direction turns to ascend up the valley. The opposite air movement occurs at night when cold air blows towards the valley bottom. Another diurnal pattern occurs in coastal areas and land areas near great lakes, where the differential heating of land- and water-masses causes a movement of air from the water towards land during the day and the other way around during night. However, this breeze phenomenon also has an annual cycle with onshore winds during summer and offshore winds during winter, as observed, for instance, in wind direction data from Nuuk with winds from the northeast during winter and from the southwest during summer (Hansen, 2001). However, it must be noted that such systematic wind patterns are dissipated when frontal systems associated with cyclones pass through.

Similar to other mountainous areas, Foehn winds are common across Greenland. The dynamically induced Foehn winds are drier and warmer than the lower lying air masses in the fjord areas, as a result of an adiabatic descent from higher elevations. Foehn

winds are common along the west coast of Greenland, whereas the colder Katabatic winds are more widespread on the east coast (Cappelen et al., 2001). The Föhn situations can bring rapid, marked changes in air temperature, for instance resulting in episodic snow melt events with subsequent consequences for the ecosystem (Pedersen et al., 2015).

Temperature and Precipitation

The Greenland Inland Ice Sheet

The surface air temperature over the GrIS varies with latitude, elevation, and albedo, and can fluctuate quite markedly between seasons. For instance, at the summit (72.6°N, 38.4°W and ca. 3200 m a.s.l.), the mean annual air temperature is -31°C , with an annual range of approx. 30°C (Fig. 4). In this central part of the GrIS, temperatures as low as approx. -70°C have been recorded (Cappelen, 2017). Moving west or east from the summit, the temperature changes with approx. 0.8°C per degree latitude (Steffen and Box, 2001).

The temperature profile over the GrIS is also strongly affected by surface inversion layers. These thermal inversions in the tropospheric thermal lapse rate are particularly formed in periods with negative surface energy balance, such as periods with low solar

Fig. 4 Mean air temperature for the whole Greenland, derived from MARv3.5.2 RCM data from 1986 to 2015 (Fettweis et al., 2017).

radiation (and thus minimal heating of the Earth's surface), and over snow- and ice-covered surfaces with high albedo. These inversions are strongest during winter (Cappelen, 2017), but also occur in the summer. Cyclones passing over the GrIS create enough atmospheric mixing to disturb the inversions. Stable conditions reappear when the cyclones have passed.

The mid- and northern parts of the GrIS are highly arid resulting from the low humidity of cold air masses, while large precipitation amounts fall especially in the southeastern part. While the inner part of the GrIS gains mass through precipitation and rarely experiences melt conditions, the main ablation occurs in the lower lying margin of the ice sheet. Ice motion transports this surplus of mass from the interior to the margins.

Ice-Free Greenland

Although the ice-free part of Greenland only constitutes approx. 20% of the island's area, it covers a great variety of climatic regimes following its extent that covers several latitudinal and longitudinal degrees. In general, the ice-free part of Greenland represents a narrow band of land strongly influenced by the above-mentioned climate at sea and over the GrIS. The northern parts are subject to continuous permafrost, while discontinuous and sporadic permafrost is found south of 70°N. In southern Greenland, most of the ice-free regions only have permafrost at high elevations (Westergaard-Nielsen et al., 2018, Fig. 5). The complexity of local gradients such as the coast-inland-GrIS transects, makes Greenland a challenging place to study climate and related processes.

Latitudinal gradients

Greenland spans more than 23° of latitude, from 59.8 to 83.6°N. This results in quite varied climates, from high arctic polar desert in the north to humid low arctic tundra in the south. The latitudinal gradient in surface air temperature is mainly controlled by incoming radiation, and temperatures have consequently been described as almost linearly decreasing with latitude (Hansen et al., 2008; Rysgaard et al., 2003). However, the aforementioned ocean currents, and particularly sea ice conditions, are also important factors in controlling surface air temperatures across Greenland (Cappelen et al., 2001). In addition, cyclonic activity plays an important role, bringing unstable weather but also slightly warmer temperatures to the areas they cross (Przybylak et al., 2003).

The largest latitudinal temperature differences exist during winter and shoulder seasons during which the greatest differences in radiation balance and sea ice conditions are found. This temperature gradient is on the other hand small during summer, when the north/south variation in incoming radiation is less pronounced due to the midnight sun north of the Arctic Circle. In July, the average air temperature in Peary Land (Northernmost Greenland) is 2–3°C and it is 4–5°C around Nunap Isuata (Southernmost Greenland; Westergaard-Nielsen et al., 2018), despite a latitudinal difference of 23°. In January, the difference is much more pronounced, with –29 to –28 in Peary Land and –12 to –11 at Nunap Isuata (1986–2015 climate normal period, Fig. 6). This winter difference is higher when storm tracks with warmer temperatures reach the southern parts of Greenland. The variation in annual temperatures are also exemplified by the number of consecutive days with temperatures above freezing, as shown on Fig. 7. This figure illustrates the marked differences between north/south as well as east/west across Greenland over the course of the year.

Generally, the amount of annual precipitation decreases with latitude due to a combination of the warmer southern air masses being capable of carrying more moisture, longer periods with open waters, and higher evaporation from the sea surface. In addition, the percent of annual precipitation falling as snow is 80%–90% in the northernmost region (Hansen et al., 2008). Reliable precipitation measurements are scarce in Greenland, but data from the Danish Meteorological Institute (DMI) suggest 100–150 mm year^{–1} in the driest parts of North Greenland, and more than 2400 mm year^{–1} in the wettest areas of southeast Greenland (data from 1961 to 1999, Fig. 7). The spatial distribution of precipitation is illustrated in Fig. 8A and B. From a hydrological perspective, the latitudinal difference also results in an interesting shift in water balance. South Greenland has a positive net water balance (i.e., there is a higher input of water from precipitation than is lost from evapotranspiration); there is a negative net water balance in North Greenland. The shift is a continuum, but goes from positive to negative north of Disko Island, at around 70°N. This variation in water balance is crucial for ecosystem functioning, including soils. The negative water balance results in upward moving water, higher salinity and even salt precipitation on the soil surface in the north in contrast to soils in the south, which are more deeply weathered and nutrient poor, due to the leaching of nutrients. Both conditions influence plant growth and the response of vegetation in the Arctic to a generally warmer climate.

Longitudinal differences

The differences in air temperature and precipitation between the west- and east coasts result from the aforementioned sea ice dynamics etc., but also from a difference in topography and the area of ice-free land. The ice-free part of east Greenland south of 68°N is limited to a narrow strip of a few kilometers between the Denmark Strait and the GrIS. The topography is mountainous with elevation differences of more than 1000 m over 2–3 km. Consequently, this coastline is a significant orographic barrier for wind masses moving west from the Denmark Strait, and it receives a factor of two to three times more precipitation than the west coast at the same latitude, according to recent modeling (Fettweis et al., 2017), see Fig. 8. Besides the sea-ice conditions, the topography also plays a role in the lower average air temperatures than on the West coast, due to the higher elevations on average (Karami et al., 2017, Fig. 9).

The west coast south of 70°N has relatively mild winters, because of the absence of widespread sea ice, while north of 70°N, both the west- and east coast have quite stable and almost continental winter climates due to a persistent sea ice cover in Baffin Bay and the Storö, respectively. Winds from northerly directions are frequent during winter at both the west- and east coast

Fig. 5 Permafrost zonation in the ice-free part of Greenland. North of 70°N, the vast majority of ice-free land is subjected to permafrost, while permafrost is only found in high elevations south of 63°N. Westergaard-Nielsen, A., Karami, M., Hansen, B.U., Westermann, S., Elberling, B. 2018. Contrasting temperature trends across the ice-free part of Greenland. *Scientific Reports* 8(1), p. 1586.

Fig. 6 Annual air temperature averages for the ice-free part of Greenland derived from MARv3.5.2 RCM data from 1986 to 2015 (Fettweis et al., 2017). Few differences in temperature can be observed in peak summer (July), while a strong north/south gradient exists during January. Westergaard-Nielsen, A., Karami, M., Hansen, B.U., Westermann, S., Elberling, B. 2018. Contrasting temperature trends across the ice-free part of Greenland. *Scientific Reports* 8(1), p. 1586.

north of 68°N, and are oftentimes associated with clear high-pressure weather at the coast (Cappelen, 2017). During winter, the low-pressure systems formed at the Polar front will occasionally pass along the Westcoast and disturb the clear weather with high wind speeds from south/southeast, precipitation, and higher temperatures, however not as frequently as during summer. A similar pattern occurs at the East coast north of 68°N, due to cyclonic activity over the Greenland Sea.

Coast-inland gradients

There are substantial differences between the climates at the outer coast and the inner fjords. Temperature differences along this gradient can be associated with the thermal properties of the ocean and land. However, Greenland is characteristic in the sense that the coast-inland gradients are usually east/west oriented, and therefore fall along the same latitude. Besides this, the coastal-inland gradients are also a continuum between the coastal zone and the GrIS.

In general, the winters are milder towards the coast with more precipitation. During summer, the coastal areas are colder than the protected inner fjord areas. This is the result of the proximity to cold waters, but it is also due to less incoming shortwave radiation during cloudy conditions, which are more frequent towards the coast. Again, the summer precipitation decreases when moving inland from the coast. For instance, Sisimiut has an annual precipitation of approx. 380 mm year⁻¹, an average summer temperature (June, July August) of 5.3°C, and –12.3 during winter (December, January, February) (data from 1961 to 1990, DMI). Kangerlussuaq, which is located on a similar latitude but 130 km further inland, receives only 150 mm year⁻¹, has an average summer temperature of 9.2°C, and an average winter temperature around –19.2°C (data from 1973 to 1999, DMI). Another example is the difference between Nuuk near the coast and Kangerlussuaq (Fig. 7).

Terrestrial Ecosystems

The primary productivity of Greenlandic terrestrial ecosystems mainly reflects summer temperatures, growing season length and precipitation. Greenland lies within the high-, low-, and sub-arctic vegetation zones. The high- and low arctic zones are separated roughly by the 5°C July isotherm, and the sub-arctic zone by the 10°C July isotherm and a growing season of 3–5 months. The sub-arctic zone is only found in the inner fjords in south Greenland. Here, low birch forests grow at protected sites, alongside shrub willows reaching 2 m in height. These areas also serve as grazing areas for sheep (Westergaard-Nielsen et al., 2015). The sub- and low arctic zones are characterized by a high biological diversity for a region experiencing arctic climate, with around 600 different species including mosses and lichens (Bay et al., 2001). The high diversity is especially found at moist and wind protected sites, but the majority of the low-lying areas in the low arctic zone are covered with a combination of vascular plants (especially dwarf shrubs), mosses, and lichens. Moving to the high arctic, the diversity decreases to approx. 100–300 species, and the vegetation is more open. Dwarf shrubs are less dominant, while lichens are more prominent. The coverage of vegetation in the high arctic areas is around 5%. Some species are found throughout coastal Greenland, such as willow and some sedges growing in moist wetlands, although the abundance of both is minimal in the north.

Fig. 7 Measured temperature and precipitation across Greenland, illustrating the differences in temperature amplitude and precipitation amounts from a coastal area (e.g., Nuuk) and inner fiord area (e.g., Kangerlussuaq). Likewise there is a distinct decrease in precipitation towards the north, resulting from the lower absolute moisture levels in the atmosphere.

The North Atlantic Oscillation and Its Effect on Greenland Climates

The North Atlantic Oscillation (NAO) is considered the most prominent and recurrent system of atmospheric variability over the mid- and high northern latitudes (Hurrell et al., 2003), which is also true for Greenland, especially during winter. It is driven by a surface pressure difference between the region around the Azores, and around Iceland. NAO is considered in a positive phase during large pressure differences and a negative phase when the difference is low. A significant positive state during winter results in stronger westerly winds over the North Atlantic and northerly winds which carry cold air from northernmost Canada and Greenland southward. This generally results in colder than average land and sea surface temperatures over northeast America and most of Greenland. The same general pattern occurs during summer, although it is less pronounced. The increase in northerly winds traveling southward over Greenland during a strong positive NAO transports low amounts of atmospheric moisture, which again results in a higher likelihood of below average precipitation over Greenland. Gridded climate data suggests that NAO-driven changes in winter precipitation are less predictable than changes in summer precipitation (Harris et al., 2014). Consequently, a strong positive NAO-phase during summer can generally increase the precipitation in southwest Greenland.

Fig. 8 Precipitation across Greenland averaged from 1986 to 2015 using MARv3.5.2 RCM data from 1986 to 2015 (Fettweis et al., 2017). (A) Illustrates rainfall, (B) Illustrates snowfall. Particularly the south- and southeast coast receives large amounts of precipitation coming with the warmer ocean currents from sub-Atlantic waters.

Fig. 9 Latitudinal differences in ice-free area and elevation. *Blue* bars and lines represent the west coast, *red* bars and lines represent the east coast. *Gray* areas represent the total elevation dataset, while the *blue* and *red* lines show the average elevation in m a.s.l. Karami, M., Hansen, B.U., Westergaard-Nielsen, A., Abermann, J., Lund, M., Schmidt, N.M. and Elberling, B., 2017. Vegetation phenology gradients along the west and east coasts of Greenland from 2001 to 2015. *Ambio* **46**(1), pp. 94–105.

A negative NAO increases the likelihood for drier than average conditions in the southern third of Greenland, and warmer temperatures across west Greenland.

NAO is known to have downstream effects reaching far into Europe and North America.

Abstract

The contemporary terrestrial ecosystems of West Greenland from ~64 to 70 °N and their environmental context are described. Regional geology is predominantly Archean basement volcanic rocks and climate ranges from maritime low arctic to continental low arctic in the dry interior with a corresponding switch from intermittent to continuous permafrost. There is a pronounced gradient in effective precipitation which is clearly reflected in surface water chemistry and vegetation. Vegetation is characterized by dwarf shrub tundra, and plant community structure reflects the overarching regional climate gradient but also local topographic controls and processes (relief, aspect, altitude). The moist outer coastal areas are characterized by *Empetrum nigrum* and cryptogams with fellfield communities at higher altitudes, while the dry, continental interior has a more relatively luxuriant assemblage of woody plants, notably *Betula nana* and *Salix glauca* where water availability permits. Closer to the ice sheet margin and at higher altitudes, landscapes are steppe-like with plant community structure reflecting the more extreme and inhospitable (cold and windy) conditions. Soil types and distribution broadly reflect these climate and vegetation gradients. The role of climate and immigration changes since deglaciation in molding the modern ecosystems are described, notably the effect of the Holocene climatic optimum and Neoglacial cooling. The effect of grazing by the two large herbivores (*Rangifer tarandus* and *Ovibos moschatus*) on vegetation and carbon dynamics are considered as well as the synergistic interactions of herbivores and vegetation with rapid climate changes (moisture stress, warming and increased late-winter precipitation) that have occurred since 1996. Recent phenological change and altered winter precipitation have driven trophic mismatches in *Rangifer tarandus* and the Greenland White-fronted goose (*Anser albifrons flavirostris*) possibly related to climate teleconnections across the North Atlantic, such as the Greenland Blocking Index.

Because 80% of Greenland is ice-covered, the diverse terrestrial ecosystems of West Greenland are contained in a relatively small area, which coupled with the strong regional environmental gradients in temperature and precipitation make it a natural experimental area. Rapid recent warming (mean June temperatures have increased by 2.2 °C since 1994) has occurred while extensive ecological research is being undertaken which is allowing critical insights into processes and linkages between temperature, moisture and external disturbances (grazing, insect outbreaks and atmospheric nutrient inputs: dust deposition and reactive nitrogen). The results of this research are providing a deeper understanding of terrestrial and aquatic ecosystem development, resilience and change, both in terms of how past processes and landscape history, natural environmental gradients shaped their formation and how they are responding to recent rapid climate change.

Introduction

Greenland is home to the second largest ice mass on Earth today. Ice covers some 80% of the island and while the ice sheet is a major focus of research, the ice-free areas include a diverse range of terrestrial and aquatic habitats. The strong environmental gradients that are created by the close juxtaposition of ice, land and ocean provide a range of natural experimental environmental scenarios that are increasingly being utilized by scientists. These longitudinal and latitudinal gradients also offer glimpses of what the ice marginal environments of the Fennoscandian and Laurentide ice sheets would have been like during the last glaciation. Moreover, the Greenland ice sheet is now changing rapidly with major implications for functioning of the earth system, through sea-level rise and climate dynamics. While the recent changes in the Greenland ice sheet are themselves representative of global warming, the changes in terrestrial communities are also indicative of wider set of problems affecting high altitude ecosystems,

namely the interaction of warming, changing precipitation with altered biogeochemistry (e.g. long-range nutrient deposition) and atmospheric pollutants. The continued decay of the ice sheet will create new terrestrial environments as previously glaciated areas are exposed but also impact those habitats that were established following its contraction from its maximal extent due to changing physico-chemical gradients at the land-ice interface (Anderson et al., 2017). Today, terrestrial environments range from the extremely unproductive polar deserts of the north and north-east to the sub-arctic birch (*Betula pubescens*) copses of the southern tip ($\sim 60^\circ\text{N}$), an area where agriculture is practiced today and human impact on vegetation is also most pronounced (Fredskild, 1992).

This contribution focusses on the terrestrial ecosystems (and associated inland waters) of west Greenland from the area around Ilulissat and Disko Island (ca. 70°N) to that around Nuuk, the provincial capital (64°N) (Fig. 1). This stretch includes the widest ice-free margin on the island, along Kangerlussuaq (Søndre Strømfjord in Danish). The region encompasses strong climatic and environmental gradients that exert considerable control on vegetation and soil processes and hence regional biogeochemistry. The interior around the head of Kangerlussuaq fjord was one of the first areas to be explored scientifically (Böcher, 1949) and the establishment of the airport has facilitated a range of research on the outlet glaciers from the Greenland ice sheet, glacial geomorphology and hydrology, as well as vegetation and lakes (Anderson et al., 2017). The contemporary vegetation distribution and

Fig. 1 Location map showing the broad physiographic nature of the study area (left) and the change in vegetation community structure between coastal and inland areas.

fauna of the area is well described (albeit in Danish mainly; see Further Reading). This synthesis briefly reviews the ecological research and attempts to integrate them in the context of recent climate change. There is also a longer-term perspective of ecosystem changes derived from paleoecological methods (Bennike, 2000). These contemporary and palaeoecological investigations coupled with some of the longest temperature records in the Arctic (Hanna et al., 2012) provide a critical context/perspective for an area that is now changing rapidly (Anderson et al., 2017).

The range of contemporary ecological research allows the effect of these recent climate changes to be viewed in an integrated fashion. Given the rapidity of recent environmental change in the Arctic and in Greenland in particular, here emphasis is placed on the effects of environmental and climatic change on integrated cross-system interactions, both biological and physical, as much as a process-based narrative of the main terrestrial habitats.

Physical Setting: Geology and Climate

Geology

The geology of Greenland is dominated by ancient crustal crystalline rocks. The central part of the western ice-free margin described here (Fig. 1) is mainly Precambrian granodioritic gneisses with localized ultra-basic intrusions which weather to create geologic and water chemical anomalies. Around Disko Island to the north of the study region there are Tertiary basalts and to the south are very old rocks from the Caledonian orogeny. The combination of hard local geology with scouring by the ice sheet has created a predominantly glacially-smoothed landscape that is dissected by the fjords cut by outlet glaciers. Because of this, and in contrast to much of northern North American and Siberia, thermokarst landscape processes are less prevalent. Locally, this rounded, relatively low relief is broken by structurally-controlled features (i.e. dykes/intrusions) while at the coast there is more vertical relief and local valley and cirque glaciers are present.

Climate

The climate of the coastal zone is predominantly low-arctic maritime with mean annual temperatures of -4.5°C , -3.6°C and -1.2°C at Ilulissat, Sisimiut and Nuuk respectively (Fig. 1). There are long-term temperature records for some of these locations which has provided an important temporal perspective on regional warming in Greenland (Hanna et al., 2012). Inland areas ($>80\text{ km}$ from the coast) experience a more continental climate (mean annual temperature at Kangerlussuaq is -5.6°C ; the annual temperature range is $>30^{\circ}\text{C}$) with warm, dry summers. There is a reduced annual temperature range ($\sim 20^{\circ}\text{C}$) at the coast where summers are cool and wet while winters are a little milder. The area is underlain by continuous and semi-continuous permafrost, the latter mainly found towards the coast. There is, however, considerable local variability: talik zones occur under larger lakes, while local relief, which influences snow cover, as well as the distribution of organic rich soils and fens can affect permafrost depth and active layer thickness. Active layer thickness varies between 0.5 and 1.5 m, with depth of the annual thaw determined largely by vegetation cover, organic matter and water content. At Qeqertarsuaq on Disko Island the thaw generally started in early June (in the sampling period 1991–1996) but with some inter-annual variability. The onset of freezing was more consistent, beginning in late-September/early-October (Humlum, 1998). Recent warming means these patterns will be changing but contemporary data are limited. Recent surveys at a lake catchment close to the ice margin observed the active layer to be $\sim 1\text{ m}$ thick at the end of August (Johansson et al., 2015).

There is a strong gradient in effective precipitation across the Kangerlussuaq area of west Greenland in part due to the rain shadow effect caused by the Sukkertoppen ice cap. Throughout the coastal zone annual precipitation can exceed 500 mm yr^{-1} . Where the terrestrial, ice-free zone exceeds $\sim 100\text{ km}$ in width, the climate of the interior becomes more continental and drier: for example, the area around Kangerlussuaq has low precipitation ($<200\text{ mm yr}^{-1}$) and evaporation exceeds precipitation during the summers. The intrusion of marine fjords into the landmass alters this general pattern as some of the longer fjords freeze in the winter, whereas the open sea south of 68°N does not. The regional climate gradient continues towards the ice sheet margin with more extreme conditions adjacent to the ice sheet: colder and windier. Winds in this area are variable but are dominated by cold, mainly easterly katabatics flowing off the ice sheet; during the winter wind speeds can reach $>30\text{ m s}^{-1}$. Warm, foehn winds also occur and, in the winter, can cause melt events and the subsequent refreeze can create ice crusts which may cause mass mortality of reindeer due to starvation.

Beyond the low mean annual temperature, two aspects of the regional climate of west Greenland are pertinent to terrestrial ecosystem development and functioning: the amount of snow accumulation at the coast and the high evaporation rates of the arid interior during the summer. Snow cover can exceed 2 m at the coast (Curtis et al., 2018), which has a pronounced impact on local hydrology in Spring, whereas inland the initial snow amounts are much lower but are also reduced by sublimation and winter thaw events by mid- to late-April (Fig. 2). Adjacent to the ice sheet, wind scouring and redeposition of snow in more sheltered parts of catchments is important.

Surface hydrology reflects the regional gradient in effective precipitation. Overland flow events during summer and streams are most obvious at the coast while in inland areas, streams only occur as outflows from lakes. Summer precipitation in the dry, continental interior, only very rarely reaches the intensity to support overland flow. Lakes are abundant across the region reaching up to 14% of the land area (Anderson et al., 2009) and their water chemistry and dissolved organic matter characteristics reflect the regional gradient in effective precipitation: lakes at the coast are dilute ($<100\text{ }\mu\text{S cm}^{-1}$) and oligotrophic while inland conductivity

Fig. 2 Photographs illustrating hydrological differences across West Greenland. A, moat at ice-out; B, fossil shorelines reflecting past high lake-levels; C, ice-dammed lake and pond in foreground; D, late-winter view near the head of the fjord showing the thin to absent snow cover. All photographs: N J Anderson.

is greater ($> 200 \mu\text{S cm}^{-1}$) with substantial major ion and dissolved organic matter concentrations (Anderson and Stedmon, 2007). Ice marginal lakes that are not fed by glacial meltwater are intermediate between these two end members in terms of their limnology and water chemistry (Whiteford et al., 2016). Close to the ice sheet there are numerous ice-dammed lakes some of which drain periodically (Fig. 2C).

At the coast, the spring thaw can be rapid (flashy) and lake hydrological retention times during the summer ice-free period are short, certainly in comparison to those inland. In terms of the water balance of lakes in the interior, the seasonal thawing of the active layer and/or the melting of any remaining snow is the main hydrological input: summer precipitation is essentially offset by evaporation. Oligosaline lakes occur between 51.5 and 50.5°W ; their occurrence reflects landscape morphology (catchment:lake ratio, absence of an outflow) as well as the low precipitation and high rates of evaporation. Reconstruction of lake water conductivity (a proxy for salinity and hence effective evaporation), coupled with $\delta^{18}\text{O}$ stable isotope records and analysis of fossil shorelines (that reflect higher lake-levels) indicate that precipitation has varied considerably throughout the Holocene in the arid interior (Aebly and Fritz, 2009). Today, lakes are responding heterogeneously to increased regional evaporation (Law et al., 2018). While some are shrinking due to evaporation, others are increasing, possibly due to the role of permafrost melting. Recent work on the effect of moisture stress dwarf shrub tundra (see below), suggests that these past changes in effective precipitation will have impacted terrestrial vegetation and carbon cycling.

Climate History

Coastal west Greenland became ice free from approximately 11.4–10 kyr BP with regional variability caused by local conditions, e.g. topography. The contraction of the ice sheet to its most easterly minimum from its maximum extent took some 2900 years. Briner et al. (2016) provide a synthesis of long-term climate reconstructions for Greenland. In the context of this synthesis, apart from the obvious constraint of the timing of ice withdrawal which permits terrestrial and aquatic community development, three aspects of Holocene climate history are pertinent for terrestrial communities and regional biogeochemistry, namely the Holocene climatic optimum, the onset of Neoglacial cooling and the Little Ice Age (see below). Although cooling for much of the late 20th century, west Greenland is now undergoing rapid warming (Saros et al., 2019).

Vegetation and Soils

Modern Vegetation Distribution

The vegetation of Greenland south of 70 °N is mainly low arctic tundra but with a clear demarcation between the coastal and inland, continental areas reflecting the regional climate gradient described above (Fig. 1). Vegetation at the coast is classified as moist [maritime] shrub tundra, with *Empetrum nigrum* as the dominant woody plant. In more sheltered areas at lower altitude there are occasional abundant expanses of *Salix glauca*. However, even at lower altitudes vegetation cover can be relatively thin and lichens and mosses are abundant. Vegetation cover decreases with altitude and snow bed and fell-field communities become more common (Fig. 3). Further north, *Cassiope tetragona* is a more typical representative of the woody tundra plants found in the southern High Arctic vegetation zone.

As one moves inland, *Empetrum nigrum* becomes less frequent and *Betula nana* increasingly common. In the dry interior, on north facing slopes the dry dwarf shrub tundra can become quite luxuriant (a mix of *B. nana*, *Salix glauca*, and *Ledum palustre* ssp. *decumbens*, *Vaccinium uliginosum* and occasional beds of *Rhododendron lapponicum*) (Fig. 4) while on south facing slopes moisture stress reduces vegetation cover to a mix of bare ground, steppe-like grasslands and fell-field communities on the hill tops (Fig. 4). At higher altitudes (> 300 m asl) closer to the ice sheet margin steppe-like communities become dominant but again with extensive bare patches due to moisture stress and wind scouring (Heindel et al., 2017) (Fig. 5).

Soils

There has been relatively little work on soils in Greenland since Böcher's initial surveys (Böcher, 1949), but recent studies have highlighted the considerable local scale variability in soil thickness and type. Given the strong regional gradients in climate, relief and vegetation from coast to ice sheet margin, the soil types and their distribution largely reflect these changing macro controls. Most soils in Greenland tend to be varieties of rego- and cryosols and given the underlying geology, acidic. Soils are often thin; cryonival and soliflucted soils are typical at the coast, occasionally thixotropic soils occur. Inland, organic rich soils accumulate (mean thickness ~50 cm but locally deeper) on the north facing slopes with little to none on the south facing ones. In valley bottoms and at slope breaks, thicker (> 1 m) fen-like, organic rich deposits accumulate. Despite recent studies there is relatively little information

Fig. 3 Photographs illustrating coastal environments and landscape. A and B, note the high relief, limited vegetation cover and emergent coastal platform due to isostatic rebound. All photographs: N J Anderson.

on the soils associated with the *B. nana*/*Salix glauca* dominated dwarf shrub tundra that characterizes much of the area between the coastal zone and the steppe-landscape close to the ice sheet margin (Fig. 5).

At the local scale, heterogeneity is a key landscape characteristic (Figs. 4 and 5) with soil type and thickness reflecting landscape age, vegetation, aspect and topography and local geomorphic processes. As a result of deflation of the fluvio-glacial deposits on the sandurs, the ice marginal zone is influenced by aeolian dust deposition and the development of loess deposits which form biological crusts. Proximity to the ice sheet is important both in terms of providing a steady supply of dust sources and exposure to strong winds that can scour and erode thin soils, with subsequent redeposition of the minerogenic fraction and loss of organics (Bradley-Cook and Virginia, 2018; Henkner et al., 2016).

The intensity of dust deposition varies both seasonally and over longer timescales (Fig. 6). Silt deposition declines with distance from the ice sheet margin/sandurs) and as wash out by precipitation increases. In the inland areas in the late-winter/early-spring in dust cover is particularly noticeable on snow patches and vegetation, reflecting peak deflation at the end of the winter following snow sublimation (Fig. 7A,B). However, the increase in the amount of late-winter snow over the last 30 years (Saros et al., 2019) is having an impact on this process. While deflation from sandurs is a regular and visible phenomenon (Fig. 7), local erosion and reworking of older aeolian deposits and its movement across catchments and between soils and lakes is more difficult to quantify (Saros et al., 2019). Given the process and timescale of the development of loess deposits and associated microbial communities this may be locally important. The implications of these processes for regional biogeochemistry are only now being addressed (Anderson et al., 2017).

Jensen et al. (2006) determined C stocks and accumulation rates on a coastal platform on Disko Island. The soils investigated developed on *Cassiope* heath and were acidic (pH range 5.6–6.4) but the oldest terraces had a pH of 4.5 indicating long-term acidification associated with landscape ageing and weathering. Soil C stocks (to a depth of 60 cm) were 2.6 ± 0.7 and 8.4 ± 2.4 kg C m⁻² on *Cassiope* heath and *Salix* vegetation cover respectively, increasing to ~ 28 kg C m⁻² in water-logged grass-dominated fens (study average: 6.7 kg C m⁻²).

Ozols and Broll (2005), in a detailed survey of 3 sampling plots ($< 40 \times 20$ m) within a small area (2×2 km) south of the large lake Sanningasoq (some 10-km east of the airport at Kangerlussuaq), showed considerable variability of soil type and geochemistry, depending on the dominant vegetation (*B. nana*, *Kobresia myosuroides* and *Salix glauca*). Carbon was enriched under *Kobresia* meadows while there was a clear acidification trend under *B. nana* heath due to organic acids associated with the accumulation of *Betula* litter.

Fig. 5 Photographs of ice marginal environments and landscape including ice sheet margin and moraines. All photographs: N J Anderson.

Bradley-Cook and Virginia (2018) reported an area weighted average soil C content of 16.4 kg C m^{-2} (to a depth of 50 cm) for the steppe-dominated landscape close to the ice sheet margin near Kangerlussuaq. There was considerable variation in C content, however, from minimal on the wind-eroded slopes to $> 22 \text{ kg C m}^{-2}$, again in moist, organic-rich fens. Average nitrogen content ranged from 0.06 to 4.85 kg N m^{-2} and the C/N ranged from ~ 13 to 20 across all vegetation types. Henkner et al. (2016) reported 14 kg C m^{-2} (30-cm depth) for an area south-east of Kangerlussuaq airport but considerable local variability related to landscape units, with aspect and vegetation type being the most important factors contributing to their classification.

As soils can be quite thin across Greenland, for a variety of reasons, carbon standing stocks are quite low compared with organic rich permafrost soils elsewhere in the Arctic. Anderson et al. (2009) suggested that given the relatively high lake density in parts of the Kangerlussuaq area lake sediments may sequester as much organic C as do soils regionally; lake sediment C burdens can approach 40 kg C m^{-2} , but there is considerable uncertainty in this estimate. However, the standing stock of soils is likely to reduce with regional warming as permafrost thaws and active layer depths increase, resulting in higher rates of organic matter mineralization. In this scenario, lakes will become important sites of carbon sequestration.

Vegetation History: Immigration and Climate

Holocene vegetation dynamics are a function of climate change, the timing of deglaciation (i.e., the creation of new habitats to be colonized), ontogenetic soil processes plant and immigration. The Holocene vegetation history of Greenland was reconstructed by Fredskild in the 1970s using pollen analysis primarily (Fredskild, 1983). Despite the limitations of this approach in arctic environments with low pollen production and limited taxonomic resolution (Pennington, 1980), subsequent plant macrofossil analyses have largely confirmed the spatial and temporal successional patterns determined by Fredskild. Bennike (2000), Wagner and Bennike (2012), and Heggen et al. (2010) provide detailed reconstructions of local vegetation change as recorded by plant macrofossils in lake sediment cores from a number of sites in west Greenland.

Recently deglaciated terrain is characterized by unstable substrates with low nitrogen availability. Lake sediment core records from W. Greenland indicate abundant cations and initial rapid weathering of the freshly communitied glacial morainic material is suggested by high $\delta^{13}\text{C}$ of the inorganic C fraction (Anderson et al., 2018). These inferences of early deglacial biogeochemistry are supported by geochemical and isotopic surveys of the present-day ice margin (Henkemans et al., 2018). Scribner et al. (2015) found that there was a greater than expected (based on the 2 to 3,000 yr difference in deglaciation exposure history) weathering gradient from the coast to the inland area, mainly due to the higher precipitation at the coast.

Fig. 6 Data plots showing changes in environmental drivers and biological response at two timescales (millennial during the A, Holocene and B, decadal changes during the 20th–21st centuries). Data taken from (Anderson et al., 2012; Boyd and Fox, 2008; Dahl-Jensen et al., 1998; Fox and Glahder, 2010; Gamm et al., 2018; Heggen et al., 2010; Saros et al., 2019).

Newly deglaciated landscapes are inhospitable and are not conducive for plant colonization and as a result are characterized by pioneer herb species, the absence of woody plants and the presence of large areas of bare ground (Fig. 5). Together with terrestrial cyanobacteria, *Dryas integrifolia* is an important early colonizer because of its ability to fix N (Heggen et al., 2010). Sediment lacustrine pigment records along Kangerlussuaq indicate abundant cyanobacterial abundance in the earliest period after lake formation,

Fig. 6 (continued).

Fig. 7 Photographs illustrating drivers of ecological change. A, dust deposits and caterpillars of the noctuid moth on rocks in the littoral zone of an ice margin lake; B, dirty snow due to dust deposition in late-April in the inland area; C, goose droppings at the margin of a lake; D, a dust storm in April adjacent to a sandur (outwash plain). All photographs: N J Anderson.

suggesting that N-limitation occurred across both terrestrial and aquatic ecosystems (McGowan et al., 2008). Wagner and Bennike (2012) inferred that this pioneer stage persisted for several thousand years at the coast due to immigration delays as much as the limited soil development. It is unlikely that temperature was a limiting factor given the rapid warming in the early Holocene and into the Holocene climatic optimum. Some support for this lack of a temperature constraint on the development of dwarf shrub tundra is provided by the occurrence of warmth-demanding herb species and thermophilous aquatic species (Bennike, 2000). In contrast, by the time the inland areas were deglaciated, the main dwarf tundra species had immigrated to Greenland and the pioneer phase was much shorter.

The development of the present-day vegetation gradient from coast to inland is reflected in the fossil record; *Betula nana* is rare in coastal lake sediment records while *Salix glauca* is more common in the late-Holocene (Wagner and Bennike, 2012). In the coastal area near Sisimiut, *Empetrum nigrum* was the first woody plant to colonize, 10.3 kyr BP and *B. nana* arrived around 4700 cal. yr BP (Wagner and Bennike, 2012). In the inland region, the period from 6500 cal. yr BP, when *B. nana* immigrated, to the start of the Neoglacial around 3800 cal. yr BP, saw the maximum extent of dwarf shrub tundra, as indicated by both pollen and macrofossil records (see Heggen et al., 2010) (Fig. 6A).

The onset of Neoglacial cooling from 3800 cal. yr BP resulted in enhanced instability and vegetation dieback across the region but responses of the terrestrial ecosystems varied between the coast and inland areas, largely reflecting the differences in precipitation and catchment hydrology. Inland, cooling was exacerbated by decreasing precipitation (increasing moisture stress) and *B. nana* abundance decreased (Fig. 6A), while at the coast vegetation dieback was coupled with increasing soil instability due to greater precipitation, relief and cryonival processes. In coastal lake-catchments, soil instability and increased erosion are indicated by lake sediment records of $\delta^{13}\text{C}$ in organic matter and the inwash of *Cenococcum* hyphae and *S. herbacea* remains (Anderson et al., 2018). In a paleolimnological study of a small lake at the head of Kangerlussuaq, Anderson et al. (2008) suggested that the dieback of *B. nana* with Neoglacial cooling had a significant effect on lake ecosystem functioning.

Biotic Interactions

Rangifer tarandus (reindeer or caribou) and muskox (*Ovibos moschatus*) are the only ungulates found on Greenland today. Greenlandic reindeer are characterized by a number of populations which have interacted to varying degrees. Two extant populations

in west Greenland are recognized (referred to as the Nuuk and Sisimiut populations) and their numbers have varied considerably over historic time. They migrate seasonally from their over-wintering grounds to a summer range where they give birth although there is some suggestion that more recently this migration has been more constricted. Historically only found in north and north-east Greenland, muskox were introduced to west Greenland in 1962 and their numbers have increased substantially since then, peaking at ~4000 in 1990, in the main due to resource availability and the absence of natural predators. Using long-term historical population estimates, both reindeer and muskox were shown to have synchronous spatial relationships across Greenland that correlated to the NAO (Post and Forchhammer, 2002).

Cahoon et al. (2012) in a field experiment near the large lake Asjuitsup Tasia (some 15-km east of the airport at Kangerlussuaq) showed that exclusion of herbivores resulted in increased shrub cover, leaf area and ecosystem photosynthesis as well as increased net C uptake by a factor of three. Simulated warming enhanced these responses but only when the herbivores were excluded. These results, although based on short-term experiments highlight the possible impact of historic variability in reindeer populations in this area on regional C dynamics.

The role of extreme events, i.e. winter warming and snowmelt, and their effect on ecosystem functioning in the Arctic is receiving increased attention. As well as abrupt, extreme weather events, fires and insect outbreaks can also have dramatic impacts on terrestrial ecosystems. On Greenland, the larvae of the noctuid moth (*Eurois occulata*) (Fig. 7) have been shown to cause widespread defoliation of dwarf shrub tundra during major outbreaks. In the Kangerlussuaq area, two outbreaks have been observed recently, in 2005 and 2011. Lund et al. (2017) estimated that defoliation reduced the C sink in their study area (Kobbefjord near Nuuk) by 118–143 g C m⁻² in 2011 but notably, the years following the outbreak there was increased primary production, possibly due to enhanced nutrient turnover rates. Lund et al. (2017) suggested that there is a role for climate in triggering outbreaks due to reduced egg mortality during warmer winters. There is the possibility of more frequent outbreaks associated with regional winter warming but their implications for vegetation dynamics and soil chemistry are difficult to predict.

Aquatic-terrestrial nutrient transfers and cross-system subsidies in West Greenland are largely unquantified but include passerines (e.g. the northern Wheatear; *Oenanthe oenanthe*) feeding on emergent (adult) diptera, for example chironomids and mosquitoes. Geese have been shown to play an important role in nutrient transfer between terrestrial and aquatic habitats elsewhere in the Arctic but there has been little work on this in Greenland, although the population dynamics of the native, Greenland white-fronted goose (*Anser albifrons flavirostris*) have been well studied (Boyd and Fox, 2008; Fox and Glahder, 2010). When molting, geese remain within a few meters of lake shores as the open water provides a refuge from predators (such as the Arctic fox); during this phase of their life cycle they defecate extensively along lake shores (Fig. 7C).

The population of *Anser albifrons flavirostris* has been declining since ~2000 (Fig. 6). The reasons for this decline are unclear but may relate to conditions in their over-wintering grounds in NW Europe and Iceland and/or climate change processes in West Greenland (Boyd and Fox, 2008) (see below). A possible contributory factor may be the rapid increases in the populations of the Canada goose (*Branta canadensis*) which have approached 40,000 over the last 30 years (Boyd and Fox, 2008; Fox and Glahder, 2010). While the two species are not in direct competition, it has been shown that the Greenland white fronted goose has a poorer dietary intake during its molting period due to pressure on its preferred resources from Canada geese (Boyd and Fox, 2008). Regarding nutrient transfer between land and water, the increase in numbers of *Branta canadensis* may be more relevant as they nest and graze on lake shores more consistently than does the Greenland white-fronted goose.

Cultural-Vegetation-Landscape Interactions

Greenland has a long history of human colonization, but two factors suggest that the historical cultural footprint is very light over much of the island: low population densities and the nature of human subsistence. As hunter gatherers with a primary use of marine resources supplemented by reindeer hunting during the summer, early Greenland settlers had limited impact on terrestrial and aquatic ecosystems functioning and hence regional biogeochemistry, despite pronounced ecosystem nutrient limitation. Given the demonstrable impact of herbivores on tundra vegetation shown by exclusion experiments, the large documented fluctuations in reindeer populations (Post and Forchhammer, 2002) may have had some impact on local vegetation and soil nutrients. Seasonal reindeer butchering sites, some of which have been used for long periods (Aasivissuit, for example, was used intermittently for ~2000 years (Grønnow et al., 1983)), where large numbers of carcasses have been processed must have had an impact on soil chemistry and perhaps the water chemistry of the littoral zones of nearby lakes. The butchering site at Aasivissuit (some 20 km west of the airport at Kangerlussuaq) is adjacent to a large oligotrophic lake (Grønnow et al., 1983). However, despite the extremely low nutrient concentrations in such large lake, any effect of the butchering process will have been confined to the littoral zone if only because of the large water volumes relative to nutrient inputs and the short, seasonal nature of the summer hunt (Grønnow et al., 1983). Some support for the localized impact of early human settlement on local biogeochemistry is, however, provided by soil and vegetation analyses of archaeological sites near Nuuk (Fenger-Nielsen et al., 2019). At all sites the soil nutrient (Olsen-P and NO₃) content around the house remains was increased relative to control sites by 2 to 6x, and vegetation structure changed as well (Fenger-Nielsen et al., 2019). They also suggested that the culturally-impacted vegetation was less affected by local climate variability. These observations, when considered in light of the results of contemporary warming and grazing exclusion experiments (see above), suggest that soil biogeochemistry may change rapidly in future decades.

Agriculture is restricted to southern Greenland today and apart from the relatively short-lived Norse occupations at the Eastern and Western Settlements (ca. 986 to 1450 AD) was not developed elsewhere. The issues surrounding the collapse of the Norse settlements are beyond the scope of this review (Dugmore et al., 2012) but there have been several recent studies using lake sediment

records to look at climate and environmental changes in relation to human settlement history on Greenland. D'Andrea et al. (2011) used alkenone-inferred temperatures to assess climate as a driver of human occupation. Over-grazing by sheep today is a problem in southern Greenland and has resulted in increased soil erosion (Fredskild, 1992).

Recent Warming and Environmental Change

West Greenland has seen dramatic increases in temperature and precipitation starting in 1994, climate changes that are having a cascading effect on regional ecosystem functioning and hence C dynamics. Since 1994 mean June air temperatures are 2.2 °C higher than the preceding 40 years and since 2006, mean July temperatures have increased by 1.1 °C. Winter precipitation has doubled from 21 to 40 mm in this time period and these changes were related to the Greenland Blocking Index (GBI) by Saros et al. (2019). There is growing evidence for phenological shifts in West Greenland driven by winter warming events and milder, earlier Springs; for example, May 2019 was 7 °C warmer than the long-term average with the growing season starting nearly 3 weeks earlier than usual.

Cahoon et al. (2016) showed that communities dominated by *Betula nana* have been stronger C sinks since 2002 in part due to the earlier start of the growing season. However, this enhanced C sink may be offset by moisture stress in the late summer. It is possible that *B. nana* may have a competitive advantage in warmer and drier conditions. However, Gamm et al. (2018) showed a major recent decline in the growth of *B. nana* in SW Greenland from (Fig. 6B) using dendrochronological and stable isotope methods. Their results indicated an air temperature of ~7 °C together with moisture limitation may be a critical in explaining the decline. *Salix glauca* also showed a decline in growth but this started later and highlights the inter-specific responses of dominant tundra species to changing environmental conditions. The decline in *B. nana* was exacerbated by moth outbreaks (see above) in 2005 and 2011 (see Fig. 6B) further highlighting the role of multiple stressors (herbivory, temperature, moisture) in determining response of terrestrial ecosystems to environmental changes in the Arctic in the 21st century.

In a study of *Betula nana* dynamics over a 100 year period on Disko Island using a tree ring record of radial growth patterns, Hollesen et al. (2015) highlighted the importance of winter climate conditions, in particular the effect of snow depth on soil temperatures as well as the timing and rate of spring thaw. Warmer spring temperatures resulted in earlier snowmelt and soil drainage and consequently soils warm quicker. They postulate that these processes may accelerate regional greening, but this conclusion has to be compared with the growing evidence for negative effects of summer moisture stress discussed above. The contrasting inferences about future trends in vegetation dynamics between the Hollesen and Gamm studies reflect to some extent the fundamental differences between maritime, coastal environments and the more arid interior in West Greenland. Despite this, changing species abundance and community composition have implications for C and N cycling in west Greenland in the immediate future.

With recent phenological changes in vegetation, Kerby and Post (2013) highlighted the cascading effect of early summer vegetation development on reindeer reproduction. This trophic mismatch is in part due to the reproductive strategy of *Rangifer*, which is an income breeder. In the latter, calving is synchronized with resource phenology—the females aim to arrive at the summer calving areas as vegetation growth is initiated; earlier springs are disrupting this relationship. Muskox in the same area have not been similarly affected as they considered to be capital breeders (see Kerby and Post (2013) for a full discussion).

Another recent climate change driven trophic mismatch may also be responsible for the decline of the Greenland White fronted goose (Fig. 6B). As discussed above, competition with *Branta canadensis* may be a factor in the decline of *Anser albifrons flavirostris* (Fox and Glahder, 2010), but the population decrease is also correlated with the recent increase in late-winter snow cover. The latter is associated with the broader weather patterns in the North Atlantic: Boyd and Fox (2008) show a link to the Atlantic Multidecadal Oscillation (cf. the GBI, Saros et al., 2019). During heavy snow years the females have reduced access to resources and as a result poorer reproductive capacity. Boyd and Fox (2008), however, consider this to be only a contributory factor in their decline as poor recruitment has also been observed during light snow years.

Synthesis: Climate-Landscape Synergies in West Greenland

The Arctic plays a key role in the terrestrial C cycle through storage of organic C in permafrost affected soils. In the future, feedbacks to the climate system will increase with enhanced organic matter mineralization and CO₂ release to the atmosphere. But these processes also release nutrients which can confound warming effects on vegetation processes. The combination of strong environmental gradients, unusual but informative abiotic and biotic events, coupled with very recent, rapid regional warming means that West Greenland offers the opportunity to understand the complex interaction between multiple stressors and ecological responses. Looking beyond the effect of temperature increases, the interaction of multiple nutrient sources (locally derived atmospheric phosphorus-rich dust and long-range transport of reactive nitrogen coupled with altered soil nutrient stoichiometry) with changing herbivore populations in West Greenland underscores the need to see arctic ecosystem response in an integrated fashion (Anderson et al., 2017). As well as this, the inland area around the head of Kangerlussuaq also offers a glimpse into a future, warmer and drier Arctic. The results of palaeoecological approaches, the availability of long-term climate data coupled with field experiments means that research on West Greenland terrestrial ecosystems offers an integrated view of past and future environmental change, with relevance both regionally and across the wider Arctic. In the early Holocene, the disjunct interactions between climate change and vegetation development brought about by delays in the immigration and colonization offer insights to possible effects of future change.

Past vegetation dynamics indicate that future changes associated with continued warming and retreat of the ice sheet may be unpredictable and reflect delays in species' immigration response, biogeochemical constraints as much as temperature forcing. Likewise, the implications for soil nutrient stoichiometry and carbon sequestration are unclear.

Further Reading

The results of many early studies on the ecology of Greenland are available in the monograph series *Meddelelser om Grønland*, much of it an invaluable historical resource. The flora of Greenland is described by Flemming Rune's (2011) *Wild Flowers of Greenland* (Gyldenlund Publishing, both English and Danish text) and a more general description of the Greenland nature is provided by Benny Génsbøl's (1999) *Naturguide til Grønland* (2nd Edition, Gads Forlag), republished in English as *A Nature and Wildlife Guide to Greenland* (2004).

This chapter focuses on west Greenland and the diversity of the research in this area, much only touched upon in this review, is highlighted by a recent special issue of *Arctic, Antarctic and Alpine Research* (volume 50, DOI: 10.1080/15230430.2018.1433786). The initial results of the long-term Danish research programme at Zackenberg (NE Greenland) are available in a special issue of *Advances in Ecological Research* (volume 40, 2008) entitled *High-Arctic Ecosystem Dynamics in a Changing Climate*. Details of ongoing long-term monitoring around Nuuk are available as report cards from the Greenland Ecosystem Monitoring (G-E-M) network (<https://g-e-m.dk/gem-localities/nuuk-basic/>).

Abstract

Greenland is the largest island of the world and is situated in the Arctic climate zone. The climate varies from humid oceanic to polar desert, and an ice sheet covers roughly 80% of the island. Sea ice is a significant factor, blocking most coasts in winter and many coasts in summer.

The bird fauna is depleted compared to other Arctic areas, due to the relatively isolated position of the island and the short history of being ice free, and most species have immigrated from their origins in Europe.

Many bird species leave Greenland for the winter to warmer regions in Western Europe, West Africa, the southern Atlantic and North and South America. However, the southwestern part of Greenland is an important winter quarter for seabirds from the northern Atlantic region.

Numerous seabirds including local breeders, non-breeders from all over the Atlantic and molting postbreeders from Canada utilize the productive seas off West Greenland in summer.

In recent decades, modern tracking methods that use electronic devices have confirmed results from previous decades of banding programs and revealed much new and exiting insights in the migratory patterns of Arctic birds.

Seabirds have been an important resource to the native Greenlanders, and some seabird populations became over-harvested due to the increased efficiency of the hunters. This is especially true for the thick-billed murre population, which do not show signs of recovery, despite improved management, while the over-harvested common eider showed a strong recovery response following a reduction in the spring hunt.

Introduction

Greenland is the biggest island in World. It is c. 2500 km long from north to south, with the northernmost point only 770 km from the geographic North Pole. It covers 2.19 million km², of which 1.8 million km² are covered by an up to 3000 m thick ice sheet, leaving a narrow fringe of land—up to 200 km wide—between the ice and the ocean on both sides. Except for a small inland sub-Arctic area in the utmost south, Greenland is within the Arctic climate zone, which means that the mean July temperature is below 10 °C. The Arctic Circle crosses the southern part of the island. Therefore, above the Arctic Circle there is continuous daylight in summer and continuous darkness in winter. Moreover, the summer season is restricted to a few months, depending on the latitude. This limits the breeding season for birds and most other life. The largest bird in Greenland, the white-tailed eagle, has a five-month breeding cycle, and must begin egg-laying by about 1 April when it is still winter, in order to fledge the young well ahead of the onset of the subsequent winter in October.

The topography of the ice-free land is generally mountainous with lowlands along coasts and in wide valleys—more extensive lowlands are only found in a few places. The widespread wet tundra seen on the North Slope of Alaska or in Arctic Siberia does not occur in Greenland. The vegetation in the lowlands is dominated by dwarf scrub heath in the dry localities, and by grasslands, fens and marshes along rivers and in other moist habitats. Extensive willow scrubs are found in the low Arctic, and a few low birch woods occur in the sub-Arctic. The vegetation cover decreases with the latitude and is, for example, extremely low in the high Arctic desert of North Greenland.

The marine environment is characterized by wide shelf waters, which in West Greenland are very productive and subject to two surface current patterns with very different properties. A cold current transporting drift ice south from the Polar Basin runs along the entire east coast, while a relatively warm current flows northwards along the west coast all the way to 76°N. This warm water usually keeps the coastal waters of West Greenland free of ice, even in winter, as far north as 68°N, and this open water area is an important winter habitat for seabirds (Fig. 1).

Fig. 1 Map of Greenland with bio-climatic zones, sea ice regime and polynyas.

The climate varies much between sites, first because of the size of the island, but also governed by the ocean currents described above. There is a strong contrast between the relatively mild and wet climate of the low Arctic southwest and the extremely dry and cold high Arctic polar desert of the far north. There are marked local variations between relatively mild and wet 'oceanic' coastlands and the more 'continental' inland areas at the same latitude. A dominant characteristic of the climate is that precipitation decreases by a factor of one hundred from south to north. This not only has a marked impact on the timing of snowmelt, but also, in combination with temperature, brings about marked differences in the regional vegetation. Trees that grow to several meters height are found only in the sub-Arctic south, while knee-high shrubs grow in much of the low Arctic, and only ankle-high vegetation is found in the high Arctic.

Seen from a bird perspective, the most significant habitat features are the duration of snow cover in spring, and the presence of sea ice and biological production in the sea.

Bird Diversity

Regularly breeding birds in Greenland include 61 species, of which 37 are associated with inland and freshwater habitats (in the breeding season) and 24 are marine birds. At least 10 other species have occasionally bred in Greenland (Boertmann, 1994). Only 11 of the breeding species are true Arctic taxa, i.e. their breeding range is restricted to this zone. Among these are brant goose, sanderling, red knot and ivory gull (Meltofte, 2013). The remaining species also breed in the temperate zone and in some cases have their main distribution there, such as the white-tailed eagle.

Inland Birds

A few inland species breed all along the ice-free areas of Greenland, such as red-throated diver, long-tailed duck, rock ptarmigan, gyrfalcon, common ringed plover and northern raven, although some of them avoid the northernmost parts. Many species are confined either to the high Arctic zone or to the low Arctic zone. High Arctic species include most of the shorebirds, the geese (snow, barnacle,

pink-footed and brant) and Arctic redpoll. Low Arctic species include the greater white-fronted goose, mallard, red-breasted merganser, white-tailed eagle, peregrine falcon, Lapland longspur and common redpoll. All of these species also occur at lower latitudes in Europe and/or North America. One species is only found in the sub-Arctic: the recently immigrated redwing.

The snowy owl and long-tailed skua are both dependent on collared lemmings as prey in the breeding season, and their ranges are similar to the range of the lemming in the high Arctic North and Northeast Greenland. However, the long-tailed skua has a very small breeding population in central West Greenland, where they live from resources in the marine environment, like Arctic skuas (Kampp, 1982). Two shorebirds, whimbrel and European golden plover, have very restricted breeding ranges in East Greenland, which must be considered as extensions of the nearby large Icelandic populations.

Even though there are more species in the inland habitats compared to the sea, the density of land birds is astonishingly low. Bird densities are especially low in the low Arctic, where only four species of shorebirds and two species of geese breed. In particularly rich habitats—such as willow copses and lush mountain slopes—densities of passerines may reach 98 pairs per km² (Frimer, 1991), but generally densities of breeding birds are much lower. The highest density of shorebirds recorded in the low Arctic is six pairs of purple sandpipers per km² (Joensen and Preuss, 1972). In the high Arctic, where 10 species of waders and four species of geese breed, densities are generally higher, and up to 17 pairs of waders per km² have been recorded (Meltøfte, 1985).

A likely explanation for the higher shorebird diversity and population densities in the high Arctic, compared to the low Arctic, is the low vegetation height in the high Arctic, combined with the availability of more snow free ground during the egg-laying season in June. This allows shorebirds to lay eggs relatively early and disperse their nests, so that it is difficult for their main predator, the Arctic fox, to find the nests (Meltøfte, 1985). The shrubbier habitats of the low Arctic are more favorable for passerines, as demonstrated by their higher diversity and density there.

In addition to breeding activities, some regions are also important molting areas for non-breeding segments of populations. Especially in the lowlands of Northeast Greenland, more than 80,000 pink-footed geese arrive from Iceland in mid-summer and spend their flightless period molting in undisturbed habitats (Boertmann et al., 2015). During the second half of the 20th century, their range has expanded considerably northward, in parallel with an extreme population increase (Mitchell, 2016), so that they now occur by their thousands, even on the barren north coast of Greenland (Boertmann et al., 2015).

Seabirds

Seabirds are generally numerous in Greenland waters, although there is high spatial variation in their population densities. The highest densities of breeding seabirds are found in the productive waters of West Greenland and in the polynyas (ice-free areas in otherwise ice-covered waters) near North and East Greenland. Widespread breeding species include the glaucous gull, black-legged kittiwake, Arctic tern and black guillemot. Species such as the great cormorant, Iceland gull, great black-backed gull and razorbill are confined to the low Arctic. Species found only in the high Arctic include the ivory gull and Sabine's gull. A number of species are more localized in their breeding range. These are restricted to specific parts of the coast, such as polynyas or areas with early break-up of the winter ice. These include the thick-billed murre, dovekie and northern fulmar, which all are extremely concentrated at these sites (Laidre et al., 2008; Møller et al., 2018). The dovekies breed at the margins of two large polynyas—the North Water in northwest Greenland and the Scoresby Sound Polynya in East Greenland. Both areas hold millions of pairs, comprising over 80% of the world population of the species (Nettleship and Evans, 1985; Kampp et al., 1987; Egevang et al., 2003). Thick-billed murres are found in large colonies at early ice-free coasts or at polynyas, with the highest concentrations in the Thule-area of North Greenland (362,000 attending individuals in five colonies in 2016) (Laidre et al., 2008; Merkel et al., 2014).

Several populations of seabirds utilize Greenland waters in summer, but do not breed there. The great shearwater breeds in the South Atlantic, but spends the southern winter in the northern Atlantic, including Greenland waters. High numbers of non-breeding northern fulmars, pomarine skuas and kittiwakes from breeding populations in Canada, Northwest Europe, Svalbard and Greenland also utilize the food-rich waters of West Greenland in summer.

The rocky coasts of Greenland provide excellent breeding localities for most of the colonial seabirds, and colonies of black guillemot and gulls are widespread and numerous. Kittiwakes and murres place their colonies on steep cliffs facing the sea. Other colonial species breed on small, low and fox-free islands. The most extreme colony sites are those of the ivory gull, as some are placed on remote nunataks up to 200 km from their feeding grounds along the coast. However, many are also found on cliffs and lowlands near the coast and even on gravel-covered ice floes or icebergs (Boertmann et al., 2010; Nachtsheim et al., 2016).

Endemics

There are no endemic bird species in Greenland, but some of the populations are considered separate subspecies that do not breed elsewhere. These include the Greenland white-fronted goose, mallard, dunlin and a number of rock ptarmigan subspecies (Boertmann, 1994).

Migration

Most of the land birds leave Greenland for the winter. However, a few can survive the winter conditions by moving south within Greenland, including the gyrfalcon, rock ptarmigan, and northern raven. Others move to the ice-free coastal environment in

Southwest Greenland, such as the purple sandpiper, mallard, red-breasted merganser, and white-tailed eagle. Gyr falcons and snowy owls even exploit seabirds in the partly ice-covered seas, far from the coast in winter (Burnham and Newton, 2011; Therrien et al., 2011).

The results of extensive bird-banding programs between the 1950s and the 1970s show that most of the land birds move southeast to winter in Western Europe and West Africa (Lyngs, 2003). The barnacle, white-fronted and pink-footed geese move to the British Isles, while one population of brant geese fly to Denmark and another to Ireland. The shorebirds move primarily to the British Isles, the Dutch-German-Danish Wadden Sea, and to West Africa. Some sanderlings migrate as far as southwest Africa in winter. Northern wheatears perform a remarkable flight from Greenland across the Atlantic to the British Isles, the Iberian Peninsula and northwest Africa in autumn (Thorup et al., 2006). Only a few Greenlandic species move to the southwest to winter in the Americas. These include the peregrine falcon that migrates to Central and South America (Lyngs, 2003), Baird's sandpiper that migrates more than 12,000 km to southern South America, and red-necked phalarope that winters on the Pacific off tropical Central and South America (Bemmelen et al. 2019). The snow buntings of Greenland disperse on two different flyways: the west Greenland birds migrate to central North America, and northeast Greenland birds to central Russia. Both populations winter in cold prairie/steppe habitats.

Among the seabirds, the migration patterns are even more diverse. This is demonstrated by data gathered from traditional bird banding, supplemented in recent decades by various electronic tracking methods. These modern tracking methods have confirmed previous knowledge about the migration patterns of Greenland birds, but they have also revealed interesting new insights into the movements, winter habitats and molting grounds of these birds. Not only does this newly acquired knowledge have important scientific value, but it has also become a very important tool for dealing with conservation issues of the species.

One of the first studies using light sensitive data-loggers (geolocators) for tracking migrating birds was on Arctic terns in Greenland and Iceland. This study confirmed the extreme long-range migration undertaken by this species as it migrates to Antarctic winter grounds. The new tracking data has also revealed how the autumn and spring movements follow different routes across the ocean (Egevang et al., 2010) (Fig. 2).

The new tracking information also identified an oceanic autumn stop-over site between the Grand Banks and the Charlie-Gibbs fracture zone (along the Mid-Atlantic Ridge between the Azores and Iceland), which later was also shown to be used by long-tailed skuas from Greenland, and by other seabird species at different seasons (Sittler et al., 2010; Boertmann, 2011).

Modern tracking methods have also contributed to a better understanding of the winter population of thick-billed murres in the important winter area off Southwest Greenland, where birds from Canada, Svalbard and Iceland mix with birds of local Greenlandic origin (Frederiksen et al., 2016).

In 2003, satellite transmitters were implanted into king eiders at a breeding site in Arctic Canada and at a molting locality in West Greenland. The birds were tracked for up to 2 years and the tracking data revealed a very important offshore winter habitat on Store Hellefiskebanke in Davis Strait. Subsequent surveys have revealed that up to half a million birds spend the winter here (Mosbech et al., 2007). A single bird circumnavigated Baffin Island (loop migration) for 2 years in a row (Mosbech et al., 2013). Satellite transmitters also tracked the movements of breeding king eiders in East Greenland to their late autumn staging grounds along the west coast of Svalbard, and to a hitherto completely unknown winter ground on the offshore Spitsbergen Bank, as well as Bjørnøya (Bear Island) (Mosbech et al., 2012b) (Fig. 3).

Fig. 2 Tracking of 10 Greenland and one Icelandic Arctic tern from the breeding sites to the winter quarter and back to the breeding site (Egevang et al., 2010), *Green* = autumn, *red* = winter, *yellow* = spring. (A) Shows birds moving along Africa in autumn and (B) birds that move along South America.

Fig. 3 Tracking of king eiders from breeding sites in Northeast Greenland to staging areas along the west coast of Spitsbergen and further on to a hitherto unknown winter quarters near Bjørnøya in Norway (Mosbech et al., 2012b).

Geolocators were deployed on little auks in East Greenland in 2007 and 2008. These revealed that after the breeding season the birds moved quickly northwards to a restricted molting ground in the Greenland Sea, where they stayed for several weeks before moving to their winter quarters on the Grand Banks (Mosbech et al., 2012a).

Greenland as Winter Quarter

It may be surprising that an Arctic area like Greenland can serve as a winter quarter for birds that breed elsewhere. Nevertheless, several seabird populations and a few inland birds from the Northern Hemisphere move annually to the very productive and more-or-less ice-free waters (and adjacent coasts) of Southwest Greenland (Boertmann et al., 2004). Most of these birds do not travel the traditional bird migration route between a northern breeding ground and southern winter quarters, but rather they migrate in an east-west direction each season. The most numerous of these birds is the thick-billed murre. More than 1.5 million individuals winter off Southwest Greenland. They arrive primarily from breeding grounds in Arctic Canada, Iceland, Svalbard and from breeding sites further north in Greenland (Frederiksen et al., 2016) and to a lesser degree from Russia (Lyngs, 2003). Common eiders are also very numerous, and the winter population is a mixture of Greenland and Arctic Canadian birds. In 2004, their numbers were estimated at 500,000, but the breeding population has grown since then, so that the winter numbers are probably much higher today. Several other seabird populations winter in southwest Greenland, including great cormorants (from Greenland), gulls, and probably large numbers of dovekies. As mentioned above, several inland birds from freshwater habitats also move to the coasts for the winter. These include local mallards, red-breasted mergansers and up to half a million king eiders from distant regions, ranging from Arctic Canada to eastern Alaska. These eiders spend the winter on shallow offshore banks (Mosbech et al., 2007). Harlequin ducks winter along southern Greenland's exposed rocky coasts, where the population is a mixture of local Greenland birds and Canadian birds.

Besides wintering in this area, Canadian king eiders and harlequin ducks perform a molt migration to West Greenland waters in summer (Salomonsen, 1968; Frimer, 1994; Mosbech and Boertmann, 1999).

Biogeography

Compared to the land bird fauna of Arctic North America and Siberia, the Greenland fauna is species-poor. This phenomenon is most pronounced among the shorebirds of which Greenland holds 11 breeding species compared to 16 species on adjacent Baffin and Ellesmere Islands, and even more diverse shorebird faunas farther west in the Canadian Arctic and in Arctic Siberia. This relatively poor bird fauna can be explained by the rather isolated position of Greenland, an island that was almost completely covered by ice during the most recent glacial period of the Pleistocene. Because of this glacial dominance, land birds have 'only' had 10,000 years to immigrate. Most likely several more species could breed there, but have not yet found their way to Greenland. Immigration is still taking place, however. For instance, two species have immigrated and established widespread and numerous populations since 1990. These are the Canada goose and lesser black-backed gull, arriving from either side of the Atlantic (Boertmann, 2008; Fox et al., 2012; Boertmann and Frederiksen, 2016). The first breeding records of these species in Greenland were recorded during a period of regional cooling (Boertmann, 2008), so recent climate changes cannot explain their arrival in Greenland, but at least their expansion there is favored by the current warming. Some of the occasional breeders may be taking their first steps towards permanent immigration, such as the tundra swan, gray plover, buff-bellied pipit, and others. Immigration of new breeding species is expected to be boosted by current climate changes; an example is that the bohemian waxwing has bred in Greenland during the past 3 years in a tree plantation in South Greenland. Another species likely to be favored by the climate changes is the redwing, which recently has established small populations in the plantations in South Greenland.

The migration routes of the different land birds and some seabird populations to some degree reflect their places of origin during the Holocene (Nørrevang, 1963). Most have apparently arrived from Northwest Europe, many using Iceland as a stepping stone. These include the white-tailed eagle and the northern wheatear. This immigration pattern has also been demonstrated by a recent immigrant, the lesser black-backed gull. Bird species of North American origin include the Canada goose, peregrine falcon, Baird's sandpiper, the great northern diver and the harlequin duck. These Nearctic migrant birds are also constrained by the long distance between the northernmost spring staging grounds and the Greenland breeding grounds (Alerstam et al., 1986), a barrier that also likely contributes to the low numbers of breeding bird species in Greenland.

Humans and Birds

Greenland has been inhabited by humans in several discrete periods since 2500 BCE, and the different populations have until recently lived primarily from hunting of mammals and birds. The Inuit ancestors of the modern Greenlanders immigrated from Arctic Canada in about 1200 CE and had a culture based primarily on seal hunting. They first established a population around the North Water Polynya, which acted as a gateway for their dispersal to most ice-free regions of Greenland. Seabirds were an important resource during some periods. One such example is the little auks that breed along the coasts of the North Water. These birds were an important food resource during summer. Until WWII, hunting was the most important occupation in Greenland, but since then a modern fishery has developed, and today only a small proportion of the population has hunting as a primary

occupation. On the other hand, hunting has become a sport and spare-time occupation, especially for the people in the larger towns. Although the Greenland population only numbers 56,000 people distributed along several thousand kilometers of coast, the hunt has had a significant negative impact on both seabird and marine mammal populations (Hansen, 2002). This is caused by a combination of human population growth, introduction of highly efficient modern weaponry, and fast motor boats. These boats put all of the coastal areas of West Greenland within easy reach of people sailing from towns and settlements. Before 1977, a largely unregulated bird hunting also contributed to the depletion of the bird populations (Mølte, 2013).

Several seabird populations in West Greenland have suffered strong decreases due to human harvesting, primarily the thick-billed murres (Fig. 4) and the common eiders, which are the most popular quarry. In the mid-1990s an estimated 200,000–250,000 murres were bagged annually, but nowadays the official bag record (Piniarneq) reports 60,000–80,000 annually, illustrating that the hunting pressure on this species has decreased. At least six thick-billed murre colonies, of which two held tens of thousands of breeding pairs, have been extirpated since the 1970s, mainly due to spring and summer harvesting of adult birds. This has also been exacerbated by the bycatch of murres in salmon drift nets, which until the mid-1970s took an estimated 250,000–750,000 murres annually, although many of the birds came from breeding sites in Canada and Svalbard (Merkel et al., 2014). Eider colonies were previously raided for eggs, and adult birds were shot in spring, resulting in the disappearance of numerous colonies, especially in Northwest Greenland (Merkel, 2010) (Figs. 4 and 5).

In 2001, hunting regulations of the common eider hunt were tightened, making the spring hunt illegal. This immediately initiated a population recovery, which still goes on today (Fig. 5) (Merkel, 2010). The regulation of the thick-billed murre hunt has also underwent changes, but due to strong pressure from hunting organizations, the regulation changes have not been sufficient, and the decrease in thick-billed murres continues. In recent years, changes in oceanographic conditions have probably also contributed to this decline (Merkel et al., 2014).

Climate Change

Climate change is particularly evident in the Arctic (ACIA, 2005), and the bird fauna is responding or is expected to respond accordingly.

Some of the most obvious signs concern range expansions, especially of low Arctic species shifting northward into the present high Arctic. Common eiders were found breeding on the north coast of Greenland in 2009, which represented a 200 km northwards extension since the 1980s, facilitated by reduced ice cover along the northern coast of Greenland (Boertmann et al., n.d.). Peregrine falcons are now observed much further north than previously, for instance in high Arctic Northeast Greenland and in 2017, Lapland longspurs have been found breeding six degrees farther north than their hitherto known range (Lee, 2018).

In the high Arctic itself, the balance between snowfall and spring temperatures is a critical habitat feature for breeding birds. Precipitation is expected to increase in high Arctic Northeast Greenland, mainly as winter snow. If this is not counterbalanced by higher spring temperatures, it may result in later snow-melt. Shorebirds are dependent on snow-free lowland areas when they arrive in late May and early June. Too much snow reduces their breeding success (Mølte et al., 2008). On the other hand, if higher spring temperatures result in earlier snow-melt, it may benefit the shorebirds in the short term, that is until low Arctic vegetation spreads across the high Arctic tundra. Most likely, we will see both phenomena: but also much higher variability and thereby a higher frequency of extreme events that may include years with high adult mortality (Mølte et al., n.d.) As these birds

Fig. 4 Development in the central West Greenland colonies of thick-billed murres since the first estimates were made in the 1930s.

Fig. 5 Development in the west Greenland colonies of common eider since the first estimates were made in the early 1800 hundred based on down trade. From Meltofte, H. (2013).

also suffer from habitat deterioration on their winter quarters, there is serious concern for the populations on the long term (Meltofte et al., 2007).

Another species expected to be affected by climate change is the ivory gull, a species associated with ice-covered seas, both when breeding and in the winter quarters (Gilg et al., 2009, 2016). The adjacent population of this species in Arctic Canada has shown a serious decline since the early 1980s (Gilchrist and Mallory, 2005), while trends in the Greenland population remain unknown, although there are signs of a decrease in the southernmost colonies (Boertmann et al., in press).

There are also signs of disrupted lemming population cycles in the high Arctic, and if they become manifest, predatory bird species dependent on this resource may suffer decreases, especially snowy owl and long-tailed skua (Schmidt et al., 2012).

On the other hand, many of the coastal species wintering in low Arctic Greenland are expected to be favored by milder winters with reduced ice cover, since winter mortality most likely is the main factor regulating the populations of these species. For example, reduced ice means increased access to seabed feeding grounds for diving ducks. Species, which could be expected to increase, both in their population size and in the size of their ranges, include the great cormorant, common eider, mallard, long-tailed duck, harlequin duck, red-breasted merganser, white-tailed eagle and purple sandpiper.

Finally, a range of species from lower latitudes may immigrate to Greenland, especially from expanding populations in neighboring countries. Seabirds like great skua and northern gannet are likely candidates (Boertmann et al., n.d.).

Bird Conservation in Greenland

Bird protection in Greenland is done through official hunting regulations, which indicate open season for the species available to the hunters. Besides closed seasons, some species also have quotas in order to limit the harvest. All other species are, in principle, protected, although the regulations are often not observed.

No areas in the populated parts of Greenland are protected from hunting and related human disturbances (except for the towns) outside the breeding season. This means there are no areas where staging coastal birds can find refuge from the threat of shooting and disturbance. Safe staging areas outside the breeding season, and particularly for coastal birds in migration periods and winter, are in high demand in West Greenland.

Only a few Greenland bird species are globally red listed according to the IUCN list of threatened species (Table 1) (BirdLife International, 2018). More species are included in the national red list (Table 1) (Boertmann and Bay, 2018).

Besides defining the open seasons, the hunting regulations also designate about 40 'bird protection areas,' which are seabird breeding colonies, where traffic and admission is regulated in the breeding season, in order to protect the breeding birds from disturbance.

Several areas are nature protection areas, but bird hunting is usually possible in these. Only in the large and remote National Park of North and East Greenland hunting is forbidden (no people live there).

The bird populations of highest conservation concern in Greenland today are white-fronted goose, thick-billed murre and ivory gull which are threatened by hunting and/or climate changes. Several other species with small populations and restricted breeding ranges, such as white-tailed eagle and whimbrel are also of concern, but their threats are less serious and can in many ways be managed.

Table 1 Red listed bird species in Greenland

<i>Red listed bird species in Greenland</i>			
<i>Species</i>		<i>Global</i>	<i>National</i>
Common loon	<i>Gavia immer</i>	LC	NT
Pale breasted brant	<i>Branta bernicla hrota</i>	LC ^a	NT
Greenland white-fronted goose	<i>Anser albifrons flavirostris</i>	LC ^a	EN
Common eider	<i>Somateria mollissima</i>	NT	LC
Long-tailed duck	<i>Clangula hyemalis</i>	VU	LC
White-tailed eagle	<i>Haliaeetus albicilla</i>	LC	VU
Gyr falcon	<i>Falco rusticolus</i>	LC	NT
European golden plover	<i>Pluvialis apricaria</i>	LC	NT
Red knot	<i>Calidris canutus</i>	NT	LC
Whimbrel	<i>Numenius phaeopus</i>	LC	NT
Sabines gull	<i>Xema sabini</i>	NT	LC
Black-headed gull	<i>Larus ridibundus</i>	LC	VU
Ross's gull	<i>Rhodostethia rosea</i>	LC	VU
Black-legged kittiwake	<i>Rissa tridactyla</i>	VU	VU
Ivory gull	<i>Pagophila eburnea</i>	NT	VU
Arctic tern	<i>Sterna paradisaea</i>	LC	NT
Common murre	<i>Uria aalge</i>	LC	EN
Razorbill	<i>Alca torda</i>	NT	LC
Atlantic puffin	<i>Fratercula arctica</i>	VU	VU
Snowy owl	<i>Bubo scandiaca</i>	VU	NT
Meadow pipit	<i>Anthus pratensis</i>	NT	LC
Redwing	<i>Turdus iliacus</i>	NT	DD

LC = Least concern, NT = near threatened, VU = vulnerable, EN = endangered, DD = data deficient.

^aApply to the entire population on species level.

Abstract

This article describes the relationship between sea ice and marine mammals around Greenland, the possible effects of climate change and the importance of subsistence hunting in modern Greenland. We also summarize the biology, conservation status and utilization of the polar bear, walrus, seal and whale species of Greenland.

Sea Ice, Climate Change and Marine Mammals in Greenland

Sea ice has a major influence on the movements of marine mammals in Greenland. Nine of the marine mammals in Greenland waters are endemic to the Arctic and associated with sea ice (**Table 1**): bowhead whale (*Balaena mysticetus*), narwhal (*Monodon monoceros*), beluga (*Delphinapterus leucas*), walrus (*Odobenus rosmarus*), polar bear (*Ursus maritimus*), bearded seal (*Erignathus barbatus*), ringed seal (*Pusa hispida*), hooded seal (*Cystophora cristata*) and harp seal (*Pagophilus groenlandicus*). The last four are also known as ice seals, as they use sea ice for whelping. In addition, cetaceans with more boreal distributions, such as rorquals (minke whale, *Balaenoptera acutorostrata*; fin whale, *B. physalus*; blue whale, *B. musculus*; humpback whale, *Megaptera novaeangliae*, and to a lesser extent, sei whale, *B. borealis*), harbor porpoise (*Phocoena phocoena*), white beaked dolphins (*Lagenorhynchus albirostris*), white sided dolphins (*L. acutus*), long finned pilot whales (*Globicephala melas*), killer whales (*Orcinus orca*), sperm whales (*Physeter microcephalus*) and bottlenose whales (*Hyperoodon ampullatus*) spend the summer feeding in ice-free Greenland waters. Also present is the harbor seal (*Phoca vitulina*), which does not necessarily associate with ice but lives in some parts of Greenland year round. The gray seal was documented in Greenland for the first time in 2009 (and observed again in 2010), but has not been reported since then. **Table 1** shows the different populations of marine mammal that are common in Greenland, together with their most recent abundance estimates, status in relation to historical levels and population trends (i.e. increasing, decreasing or stable), when known.

The Arctic is warming twice as fast as the rest of the planet (see refs in [Laidre et al., 2015a,b](#)). In Greenland, the open water season has increased by about 10 days per decade since the 1970s ([Stern and Laidre, 2016](#)). One expected consequence is that the range of the nine Arctic species will shift northwards following their preferred temperature ranges and available sea ice habitat, while the boreal species will extend the period of time they are in Greenland, and move into habitat not previously available. For ice-dependent species like the ice seals and polar bear, we expect that the reduction of sea ice will cause declines in body condition, reproduction, survival and abundance.

Regions Around Greenland and Seasonal Marine Mammal Occurrence

Based on the seasonal changes in sea ice and movement patterns of marine mammals, the seas around Greenland can broadly be divided in four general regions (**Fig. 1**).

Northwest Greenland: In Baffin Bay, sea ice forms during fall and winter in the west and north, advancing from Canada to Northwest Greenland. Polar bears range over the sea ice, while walrus, bowhead whales, narwhals and belugas follow the ice formation from Canada to Greenland. During spring and summer, the sea ice melts from the southeast to the northwest, and many of the animals return to their summer grounds in the Canadian Arctic and the boreal cetaceans and harp seals move in.

North and Northeast Greenland: In North and Northeast Greenland, there is year round multi-year sea ice, with nearly total to partial coverage during winter, except for the polynyas. Polynyas are areas of open water surrounded by ice during winter, kept open by strong currents and winds. The North Water Polynya (NOW) is located between Northwest Greenland, and Ellesmere

Table 1 Populations or management stocks of marine mammals in Greenland, with known abundances, status and trends.

Island, while the North East Water Polynya (NEW) is at the northernmost part of East Greenland. Polynyas are important for marine mammals, especially walrus and beluga in the NOW and walrus and bowhead whale in the NEW. Narwhals, bearded seals, ringed seals and polar bears use the polynyas, as well as other areas with higher concentrations of sea ice. Kane Basin lies to the north of the NOW and is important habitat for polar bears.

Fig. 1 Marine mammals areas of Greenland.

Southeast Greenland: During winter or early spring, the fjords of Southeast Greenland freeze, while the offshore areas are dominated by drift ice transported from the north by the southern flow of the East Greenland current. Polar bears, ringed seals and bearded seals thrive in the frozen fjords. In summer, the sea ice in the fjords melts and the amount of drift ice offshore gradually decreases. Several fjords are dominated in summer by freshwater ice coming from calving glaciers. Polar bears, narwhals, ringed seals and bearded seals retreat mainly into glacier dominated fjord systems, while harp seals, rorquals, pilot whales and killer whales move into the open coastal waters. Sperm whales and bottlenose whales stay in the deeper waters.

Southwest Greenland: The East Greenland Current (ECG) mixes with a branch of the north Atlantic current, along the southeast Greenland coast. The current transports sea ice, bearded seals, ringed seals and polar bears from the east to the west around the southern tip of Greenland. The current transports sea ice north along the west coast for about 200 km, with a peak around July. Polar bears are regularly seen in the southernmost part of Southwest Greenland, while walrus, narwhal, and beluga are occasional stragglers. The beluga population that migrated to the fjords of Southwest Greenland from autumn to June was extirpated by hunting last century. The southern tip of West Greenland is the only place in Greenland where all 6 species of seals from the North Atlantic have been seen (ringed seal, bearded seal, harp seal, hooded seal, harbor seal and gray seal). The boreal cetaceans, especially rorquals and harbor porpoise are abundant in Southwest Greenland.

Marine Mammals and People in Greenland

Hunting: The ancestors of Greenlanders were Inuit that came from Arctic Canada, traveling over the sea ice with dog sledges and by sea with kayaks and umiaqs ("women boats"). Marine mammals were a fundamental part of their diet. Even though human's diet in Greenland is nowadays supplemented with imported products and agriculture is developing in Southern Greenland, marine mammals are still hunted for subsistence and their products are an important part of the local economy. Hunting provides food for subsistence hunters and their families, as well as food for sledge dogs. Hunting also provides a source of revenue, through the sale of animal products, including meat, mattak (whale skin and blubber, spelled "muktuk" in the Western Arctic), fur from seals and polar bear and narwhal or walrus tusks. The challenges imposed by climate change on subsistence hunters in Greenland include a shortening of the season when it is safe to travel over sea ice with dog sledges and snow scooters. Some winter routes have become unsafe. As a consequence of the reduction of sea ice, the population of sledge dogs is dwindling. Skiffs are used more than

before for fishing and hunting and in some areas, especially in Southeast Greenland, hunting during summer has shifted from narwhals to dolphins, pilot whales and killer whales.

Management: Greenland is a country under the kingdom of Denmark, with a high degree of autonomy in several areas, including, since 1979, the management of wildlife. The Greenland Institute of Natural Resources (GINR), established in 1993, conducts research and monitoring to provide the Government with management advice to secure that fishing and hunting are sustainable. Much of the marine mammal research and monitoring work is done in coordination with organizations regulated by international government agreements. Thus, GINR presents research and monitoring results to the scientific working groups of the relevant organizations and, after a review of results and an assessment process, the organizations provide advice to the management authorities of the government of Greenland. The government then takes this advice, together with input from hunters, to decide upon regulations such as hunting seasons or quotas.

The international organizations that advise Greenland include the International Whaling Commission (IWC) for large whales; the North Atlantic Marine Mammal Commission (NAMMCO) for pinnipeds and cetaceans; the Canada/Greenland Joint Commission for the Conservation of Narwhal and Beluga (JCNB) for narwhals and belugas in West Greenland; a working group under the International Council for the Exploration of the Seas (ICES), the North Atlantic Fisheries Organization (NAFO) and NAMMCO for harp and hooded seals and the Canada-Greenland Joint Commission on Polar Bear for polar bears in Baffin Bay and Kane Basin. Management of Polar bears in all of Greenland is done following the 1972 Agreement on the Conservation of Polar Bears under the Polar Bear Range States Agreement, whose scientific advisor is the Polar Bear Specialist Group of the International Union for the Conservation of Nature (IUCN). Effects of trade in endangered species are overseen under the Council for International Trade of Endangered Species (CITES).

Biology, Status and Utilization of Marine Mammals in Greenland

Polar Bear

Polar bears are dependent on sea ice for all aspects of their life, including travel, breeding and foraging for ice seals. In the areas where the sea ice melts annually during summer, polar bears either fast on land, spend the summer on multi-year sea-ice, or spend the summer near glaciers where limited opportunities for feeding on seals resting on glacial ice may arise.

There are 19 subpopulations of polar bears around the Arctic, five of which live in Greenland: Baffin Bay, Kane Basin, Arctic Basin, East Greenland and Davis Strait (Table 1).

As of the 2010s, polar bears from the Baffin Bay subpopulation are showing effects of reduced sea ice and a longer open water season. These include smaller home range, northwards shift of the subpopulation range, more time fasting on land during the open water season, reduced body condition, maternity dens built on higher ground and shorter maternity denning periods (SWG, 2016).

In contrast, the Kane Basin population, that occupies the small area with multi-year ice in the far north, between North Greenland and Ellesmere Island, appears to be stable or increasing. This is likely because the multi-year ice is transitioning to annual ice which is more productive, and the hunting pressure by humans is lower than before (SWG, 2016).

There are fewer polar bears in the Arctic Basin than in other parts of the Arctic (IUCN/PBSG, 2019). The area, especially the parts close to North Greenland and the Canadian Archipelago, will likely be important for polar bears in the future, as the thick multiyear ice will melt and transition to seasonal ice, which is good habitat for seals and polar bears. This is expected to be the last refuge for polar bears across the Arctic when the southern parts of their current habitat disappear because of climate change.

In East Greenland polar bears occupy areas with reduced sea ice habitat and their habitat use has changed (Laidre et al., 2018). The abundance of polar bears in East Greenland is unknown, as is the connectivity of bears along the coast. An assessment of East Greenland polar bears is ongoing and our knowledge will increase considerably during the 2020s.

The Davis Strait population of polar bears was assessed as stable, with basis on an inventory terminated in 2007. Fieldwork for a new census based on genetic mark recapture was carried out in 2017 and 2018. Davis Strait polar bears spend the summers in Canada and only a small part of their range is in Greenland, when the sea ice forms during winter. As the extent of sea ice recedes due to climate change, the proportion of polar bears from this subpopulation wintering in Greenland is becoming smaller.

Polar bears are classified as Vulnerable under both the global Red List (<https://www.iucnredlist.org/>) and Greenland's national Red List (<https://natur.gl/leksikon/roedliste/>) because it is probable that the world population will be reduced by 30% between 2015 and 2050 due to reductions in sea ice.

Polar bears are important for human subsistence in Greenland, however loss of sea ice and the introduction of hunting quotas in 2005 have also increased human-bear conflicts where polar bears that approach towns and settlements are being killed to protect human lives and property. During 2017–19, an average of 143 polar bears were taken annually in Greenland, including an average of 7 taken in defense of life and property (Anon, 2019; Wilken, 2019).

Atlantic Walrus

Walrus are social animals. They haul-out for resting over land or over sea ice and feed on shellfish at the seabed in waters shallower than 50 m. Feeding bouts can last 3–4 days, followed by 1–2 days resting. There is some degree of sexual segregation, where females and calves tend to spend summer months further north than the adult males. Mating occurs during winter, in waters with high concentrations of sea ice. Seasonal movements follow the formation of sea ice, with walrus spending summers close to land

and winters close to the ice edge (Born, 2011, 2017). There are three populations of walrus in Greenland: Baffin Bay, West Greenland Winter Aggregation and East Greenland.

Walrus in northern Baffin Bay spend summers along the northeastern coast of Arctic Canada, mainly off Ellesmere Island, and winter on the Greenland side of the North Water Polynya (Heide-Jørgensen et al., 2017).

Similarly, some of the walrus that summer in Southern Baffin Island spend winters feeding on the shallow banks off West Greenland.

In East Greenland, walrus are abundant only in the National Park. An interesting feature of the walrus in East Greenland is that many males migrate hundreds of kilometers north to spend winter with the females in the North East Water Polynya (Born, 2011).

Atlantic walrus are listed as Near Threatened in the global red list. The populations in Baffin Bay and West Greenland are increasing, recovering from previous hunts, and listed as Vulnerable in the Greenland Red List. Walrus in East Greenland are listed as Near Threatened in the Greenland Red List, which is a more favorable status.

Greenlandic hunters reported taking an average of 157 walrus per year in 2016–18 (<https://nammco.no>). Nowadays, the Greenlandic subsistence hunt is sustainable. However, in the period 2013–15, catches in Baffin Bay were higher than the scientific advice from NAMMCO, which led to a self-imposed ban on export of walrus products in July 2016. This ban had not been lifted at the time of writing this text.

Past hunting has resulted in walrus being rare in some of their original range in Greenland. This includes East Greenland, south of the national park, where they no longer use terrestrial haul-outs, and current catches consist of stragglers from the north (Born, 2011). Today, walrus in West Greenland haul out almost exclusively on sea ice and their former haul-out sites on land have been abandoned for at least 50 years (Born, 2017).

Seals

There are five or maybe six species of seals inhabiting the seas around Greenland. Four of them are strongly associated with sea ice, and depend on ice for whelping, molting and resting. The remaining two species, the harbor seal and the gray seal, are coastal seals that haul-out on land. The majority of the seals of these two species live in temperate waters. Some small harbor seal populations however, live permanently in the Arctic (including Greenland) and a few gray seals may sometimes stray into Greenland waters.

Ringed seal: Some ringed seals (especially adult seals) maintain breathing holes in the ice throughout the winter and others (especially juvenile seals) winter in areas with light ice conditions, where they do not need to maintain breathing holes. They are generally solitary, although a few seals may share one breathing hole and rest beside it during molt in spring and early summer. Ringed seals make birth lairs in compact snowdrifts that are associated with a breathing hole. They feed on fish, such as polar cod and Arctic cod and are, themselves the favored prey of polar bears in most areas. Ringed seals are widely spread throughout the Arctic and are listed as Least Concern in both the global and the Greenland red list.

Ringed seals are important for the subsistence economy of Greenlanders in some regions. The average annual reported catches during 2012–17 were 56,000 seals (<https://nammco.no>). The meat is food for humans and sledge dogs. The national tannery purchases many of the skins.

Bearded seal: Bearded seals eat fish and invertebrates found on the seabed. They live alone or in small groups, in close association with sea ice, which they use for whelping and resting, especially during molting. They have a circumpolar distribution in the Arctic. East and West Greenland probably have separated stocks, but their population status and trends are unknown. Both the IUCN and Greenland Redlists have bearded seals as Least Concern.

The average annual reported catches during 2012–17 were 1200 seals (<https://nammco.no>). This hunt is likely sustainable, as bearded seals only are hunted in a small part of their wide distribution area. The skin from bearded seals is tough compared to that from other seals and often used to make soles for kamiks (Inuit footwear) and the whips used to guide the sledge dogs.

Hooded seal: Hooded seals have an impressively wide home range. They feed along the continental shelves in the North Atlantic and dives to depths of 1652 m have been recorded (Andersen et al., 2013). They mainly feed on large fish and squid. Females give birth on sea ice in March to April and they only nurse their pups for 4 days, after which they mate again and leave the whelping area. Pups remain alone on the ice for a few days, before taking to sea, spreading and learning to feed by themselves. There are two stocks in the North Atlantic, one in the Northwest Atlantic (whelping in the Gulf of St Lawrence, off Newfoundland and in the Davis Strait) and one that whelps in the Greenland Sea. Hooded seals from both stocks swim in and out of Greenland's waters. Based on surveys conducted in 2005, the West Atlantic population was estimated to be around 600,000 seals (Hammill and Stenson, 2006). No full surveys have been conducted since then and the present population trends and status remain unknown. The Greenland Sea stock decreased during a period with very high catches following the Second World War. The stock has now stabilized at a low level and Hooded seals are therefore listed as "Vulnerable" in both the global and the Greenland Red List.

There is no longer commercial sealing on hooded seals. The average annual reported subsistence catches in Greenland during 2012–17 were 1700 seals almost exclusively from the West Atlantic population (<http://nammco.no>). This catch level should not have any noticeable effect on the populations.

Harp seal: Adult harp seals often swim in large groups when foraging during summer and fall. They forage in most of the Greenland waters that are not ice covered, from offshore open water to deep inside fjords and close to glaciers. They feed on a variety of fish and invertebrates, but small schooling fish, especially capelin, but also polar cod and sand lance seem to be the most important. The West Atlantic harp seals give birth off Newfoundland around the start of March, whereas the population in the Greenland Sea

whelp about a month later. At the beginning of this century a small group of harp seals (around 1000) started to give birth on the drift sea ice off Southwest Greenland (Rosing-Asvid, 2008).

Overharvest greatly reduced the North Atlantic harp seal stocks as long ago as the 19th century, but regulations of the catches since the 1970s have allowed a strong recovery (Hammill et al., 2015). Harp Seals are listed as “Least Concern” in the global and the Greenland Red Lists.

The subsistence catch of harp seals is important in most parts of Greenland. The average annual reported catches in Greenland during 2012–17 were around 59,000 seals (<http://nammco.no>). The main purpose of the catch is to obtain meat for human consumption and for dog food, but hunters also sell skins to the national tannery.

Harbor seal: During molting and breeding, harbor seals concentrate in colonies that in Greenland typically are on small off shore rocks or sandy beaches inside fjords. Their diet includes arctic char, and some groups summer near estuaries and river mouths where this fish is abundant. Harbor seals are the only seal in Greenland that frequently swim up rivers. Although probably never numerous, harbor seals were once spread over much of the West Greenland coast. Due to excessive hunting and perhaps interactions with fisheries, harbor seals disappeared or became extremely rare throughout most of their former range. Harbor seals are now only regularly observed at three breeding/molting localities, but observations of individual seals and small groups of seals far from these localities, indicate that other small remnant populations still exist. Harbor seals are listed as of Least Concern in the global Red List, but are Critically Endangered in the Greenland Red List.

The skin from harbor seals are traditionally used in the women’s national costume and therefore specially coveted but hunting of this species has been banned in Greenland since 2010.

Gray seal: Gray seals were not conclusively documented in Greenland before 2009, when two seals were photographed during an inventory in a colony of harbor seals, near the southernmost tip of Greenland (Rosing-Asvid et al., 2010). The following summer, a gray seal pup was live-captured by scientists in a net in the same area, and it had a satellite-linked transmitter glued to its back. Unfortunately, the tag only lasted for 29 days during which the seal swam 224 km up along the Greenland east coast. This capture is the last documented contact with a gray seal in Greenland.

Arctic Cetaceans

There are three arctic whales that live year-round in Greenland: Bowhead whale, narwhal and Beluga. These are cold water species endemic of the Arctic, often associated with sea ice.

Bowhead whale: The bowhead whale is, together with blue and fin whales, one of the largest animals of Greenland. They feed on copepods, small zooplankton found in productive areas. In West Greenland, bowhead whales are especially abundant in Disko Bay, where they arrive during winter. Bowhead whales prefer water colder than 2 °C, so they leave Disko Bay in June, when water temperatures begin to increase, even though this means they miss the peak on abundance of *Calanus* prey at the surface (Chambault et al., 2018). The bowhead whales coming to Disko Bay are primarily mature females in resting year without calves (Heide-Jørgensen et al., 2010). They belong to the larger East Canada–West Greenland (ECWG) population.

Bowhead whales may reach ages of more than 200 years, were hunted to near extinction in East Greenland during the 18th and 19th century, and severely depleted in West Greenland during the 19th and 20th century (Cooke and Reeves, 2018 and references therein). They were protected worldwide by the League of Nations in 1932. By then, they were thought extinct in East Greenland and rare in West Greenland. After the 1990s, bowhead whales in West Greenland showed a steep recovery, to the point that, in 2009 the IWC agreed to give Greenland a quota of 2 whales per year for subsistence whaling. However, no bowhead whales were caught in Greenland between 2016 and 2019.

Bowhead whales in East Greenland belong to the East Greenland–Svalbard–Barents Sea population, also called the “Spitsbergen stock,” which shows small signs of recovery. The population nowadays is in the hundreds. This is a difficult population to study because the whales keep themselves inside areas with high density of sea ice.

The EGSBS population is listed as endangered in the IUCN Red List, while globally, bowhead whales are listed as Least Concern. The Greenland red List lists bowhead whales in West Greenland as Nearly Threatened and in East Greenland as Vulnerable.

Narwhal: Narwhals swim in groups, often spread over a large area in clusters made by a few animals of the same gender, such as only males or only females with calves, swimming very close to each other. Narwhals can live to be 100 years old and, together with humans, are one of the few species in which females live a considerable part of their life after menopause. The male’s left tusk is a very long tooth which pierces the skin of the upper lip and grows in a spiral form in front of the head. In medieval times these tusks were believed to be unicorn horns. It is a sexual trait that males use to establish dominance and hierarchy. Narwhals can dive to more than 1700 m to feed on Greenland halibut, although can also find their prey, including squid, shrimp and fish at depths of 200–600 m (Watt et al., 2015). Narwhals spend summers in fjords with glacier fronts. They have a high degree of site fidelity and return to the same areas every summer (Heide-Jørgensen et al., 2015). During winter, when the fjords freeze, narwhals migrate to offshore areas with high concentrations of sea ice. Narwhals from several summer stocks in Arctic Canada and Northwest Greenland mix during winter in areas with high concentration of sea ice of Baffin Bay, Davis Strait and West Greenland (Heide-Jørgensen et al., 2013b).

The global Red List lists narwhals as Least Concern, while the Greenland red list considers them Nearly Threatened in West Greenland and Endangered in East Greenland. Greenlanders are highly motivated to hunt narwhals because their mattak (skin

and blubber) is a delicacy and sells for high prices. A yearly average of 445 narwhals were reported hunted in Greenland in 2016–18 (<http://nammco.no>). The smallest populations are at the edge of their summer range in Melville Bay in Northwest Greenland and south of the National Park in East Greenland (i.e. south of 72°N), where they are decreasing in numbers due to unsustainable hunting, warming temperatures caused by climate change and disturbance from increased boat traffic (NAMMCO, 2019).

Beluga: Belugas and narwhals belong to the same family, Monodontidae, and can produce hybrids (Skovrind et al., 2019). Belugas swim in groups and feed on pelagic fish, such as arctic cod (*Boreogadus saida*). A large population of belugas spends summers in Arctic Canada, then migrates every winter, when the sea freezes, to West Greenland. Some of them overwinter at the North Water Polynya, while others continue following the ice edge to Midwest Greenland. Until the early 1920s, there was another aggregation of belugas that lived most of the fall, winter and early summer in the fjords of Southwest Greenland. The belugas of Southwest Greenland were driven to extinction by unsustainable hunting (Heide-Jørgensen, 1994).

Belugas are listed as least concern both in the global and the Greenland Red List.

The Arctic Canada—West Greenland population is hunted and was in decline during the second half of the 20th century. Because of the reduction of sea ice due to climate change, the preferred habitat for the belugas, which is by the ice edge, is getting further away from the coast of West Greenland, and they have become less accessible to Greenlandic hunters. This, together with the introduction of quotas in 2005, resulted in a reduction of catches and the population is therefore increasing (Heide-Jørgensen et al., 2016a). During 2016–18, a yearly average of 204 belugas were landed in West Greenland (<http://nammco.no>). In East Greenland, belugas are only occasional vagrant visitors and protected by law.

Boreal Cetaceans

Boreal cetaceans visit the ice-free waters of the Arctic and other northern seas during summer and migrate to warmer waters during winter. In Greenland, these include four rorquals and six toothed whales.

Rorquals: Rorquals are baleen whales with grooves on their throat. The grooves allow the mouth cavity to expand, gulping large quantities of water to trap prey such as schooling fish or krill. The five species of rorquals in the North Atlantic are the minke whale, fin whale, humpback whale, blue whale and sei whale. They all migrate from southern breeding grounds in the winter to northern feeding grounds in the summer, including the ice free waters of Greenland. Rorquals produce low frequency sounds, and the increasing levels of sound pollution in the ocean probably have an effect on the ability of rorquals to communicate with each other over long distances. Unsustainable whaling by industrialized countries depleted most stocks of baleen whales during the 20th century. However, numbers are recovering because of whaling regulations. In the global Red List, minke whales and humpback whales are listed as Least Concern, while fin whales are listed as Vulnerable and blue whales and sei whales are still listed as endangered. In the Greenland red list, minke whale, fin whale and humpback whale are listed as Least Concern, Blue whale as Vulnerable and sei whale as Endangered.

During 2016–18, Greenlanders caught a yearly average of 141 minke whales, 4 humpback whales and 8 fin whales for subsistence (<http://nammco.no>). Blue whales and sei whales are protected in Greenland.

Harbor porpoise: Harbor porpoise is the smallest cetacean in the seas around Greenland. They usually swim alone or in small groups and feed on several species of fish and squid. Harbor porpoise tagged in the summer in Southwest Greenland traveled long distances during winter, into deep oceanic waters close to the Azores and offshore waters of East Greenland, and returned to the coastal waters of Southwest Greenland the following summer (Nielsen et al., 2018). Thus, Greenland harbor porpoises travel over longer distances than porpoises tagged in the North Sea. They also dive deeper, with average depths of 248 m and a maximum depth of 410 m.

Harbor porpoise are listed as “Least Concern” in the IUCN Red List and in the Greenland Red List.

The average yearly subsistence catch in the years 2015–17 was 2275, according to hunter’s reports (<http://nammco.no>). This number is higher than the 1869 recommended by NAMMCO (NAMMCO, 2019).

Delphinids: Four species of the dolphin family use the seas of East and West Greenland during the open water season: killer whale, long finned pilot whale, white beaked dolphins and white sided dolphins. White sided dolphins are rare so far north, and their distribution may be limited to the southern parts of Greenland. They are all social animals that swim in groups.

Before 2009, killer whales were seen (and hunted) without clearly regular patterns; every year they would show up at different places of Greenland and during different months. That is still the case in most of Greenland, except from Southeast Greenland, where they are hunted every year since 2009 (Jourdain et al., 2019). A similar situation applies for pilot whales and white sided dolphins, except that these two species are more abundant in Greenland. The increased occurrence of boreal cetaceans in Southeast Greenland is probably a result of climate change, with the sea being warmer, less sea ice coming from the north with the East Greenland Current and boreal fish species moving in.

Killer whales from East Greenland are genetically related to killer whales from Iceland and Norway (Foote et al., 2013). The majority of killer whales in Iceland and Norway feed on herring, while the killer whales in East Greenland feed on seals, whales and fish. This is interesting because killer whales in other parts of the world have cultural traditions regarding food and hunting techniques, specializing in either fish or marine mammals (review in Jourdain et al., 2019).

Dolphins and pilot whales feed on fish and squid. However, dolphins feed relatively close to the surface, while pilot whales are deep divers. Pilot whales occasionally feed on other marine mammals.

Killer whales are listed as Data Deficient in the global and Greenlandic Red Lists. Pilot whales and white beaked dolphins are Least Concern in both lists, while white sided dolphins are Least Concern in the global Red List and Data Deficient in the Greenland Red List.

Average reported yearly catches in Greenland in 2015–17 were 12 killer whales, 289 pilot whales and 108 dolphins (<http://nammco.no>). The North Atlantic Marine Mammal Commission has not assessed whether these catches are sustainable, but advises Greenland to regulate the catches of killer whales, as it is not known if the killer whales caught in Greenland belong to a small population or not (NAMMCO, 2019).

As top predators, killer whales accumulate chemical pollutants consumed by their prey and by the prey's prey. This pollution is magnified through the food chain from phytoplankton to zooplankton to fish to marine mammals to killer whales. This process of magnification occurs in all marine mammals, but because killer whales are the absolute top predator, and have long live spans, they are also much contaminated by chemical pollutants, to the point that the pollution may affect their survival and fertility (Desforges et al., 2018). Killer whales, pilot whales and dolphins are used as food for humans and sledge dogs in Greenland. In 2018, the health authorities in Greenland issued a press release recommending people to abstain from eating killer whale products, as it may be unhealthy due to its contaminant load. An ongoing study indicates that contaminant levels on pilot whales and dolphins in Greenland may also be high (Roos et al., 2019).

Sperm whale and bottlenose whale: The two largest toothed whales are the sperm whale and the bottlenose whale. They are both inhabitants of deep, offshore waters, although sperm whales venture into the deep fjords of Greenland. Bottlenose whales swim in groups that include males, females and calves. Sperm whales have a strong sexual segregation, with females and calves living in groups in tropical and subtropical waters, while males move to feed at high latitudes. Thus, there are only male sperm whales in Greenland. Sperm whales and bottlenose whales are both deep divers that hunt squid and deep-water fish such as halibut.

Both species were hunted by European and North American whalers for their oil in the 20th century, while sperm whales were caught in the 18th and 19th century as well. Sperm whales were depleted in the North Atlantic but have been protected globally since the 1980s and their numbers have increased. The conservation status of bottlenose whales is not known, but they seem to be abundant. Sperm whales are listed as Vulnerable in the global and Greenland Red Lists, while in both lists bottlenose whales are listed as Data Deficient.

Sperm whales are protected in Greenland. It is legal to hunt bottlenose whales, but their meat is believed to have a strong laxative effect and therefore Greenlanders do not consider them edible. Both species are known for "stealing" halibut from fishing lines and have been unpopular among fishermen. Nowadays, however, offshore fisheries in Greenland waters are carried out by trawlers and there are no conflicts with these species.

Conservation Status of Marine Mammals in Greenland

Of the 55 stocks of marine mammals from Greenland listed in **Tables 1**, 26 have an unknown status, 23 are stable or increasing, four are in decline and one was extirpated in the 1920s. Most of those with unknown status appear to be numerous and are either protected or harvested in a sustainable way. Thus, we can conclude that the majority of marine mammals in Greenland are managed on a sustainable way, and many of the populations that have declined because of overhunting in the past have recovered or are now recovering. There are a few exemptions, though.

NAMMCO has voiced concern for the unregulated catches of killer whales in East Greenland, as the size of the population has not been assessed and they may already be compromised by high levels of contaminants (NAMMCO, 2019). It remains to be seen if the recommendations by the health authorities to limit the consumption of killer whale meat will have an effect on the number of killer whales taken by subsistence hunters.

Reported catches of harbor porpoises are higher than recommended by NAMMCO (2019), and there is a risk for population decline. However, there are still tens of thousands of porpoises in Greenland, so their population is not facing imminent risk of extinction.

Harbor seals were almost wiped out from most of their range in West Greenland. Since their protection in 2010, the colony of Cape Farewell, at the southern tip of Greenland has become larger. In other locations however, harbor seals are still rare. It seems like their recovery is hampered by poaching, entanglement in fishing gear or accidental hunting as they are mistaken for other seals and shot in open water.

As a species, narwhals are not in the risk of extinction yet, since they are protected in the national park of Northeast Greenland, and relatively abundant in north Greenland north of the North Water Polynya and in arctic Canada. However, the small populations at the southern edge of the narwhal's summer distribution, in Melville Bay (Northwest Greenland) and East Greenland south of the national park, are the ones most affected by warming climate. Those small populations are also under increasing stress from boat traffic and, most importantly, they are under pressure from unsustainable subsistence hunt and their future is uncertain (NAMMCO, 2019).

Narwhal, beluga, bowhead whale, walrus, polar bear and ice seals are endemic of the arctic and their survival depends on sea ice and cold temperatures. They are or will be negatively affected by climate change, their ranges are expected to shrink northwards and their long term future depends on the global actions taken by people and governments during the next few decades to reduce the emission of greenhouse gases.

Abstract

Greenland represents the most northern human habitation in the world. The climate is high arctic, arctic and in most southern region subarctic. The first human migrations happened c. 4,500 years ago into the Thule region from Ellesmere Island, Canada. This group of people is archeologically defined as Palaeo-Eskimos and has a cultural origin in Alaska and Siberia. During the following 3 millennia, different Palaeo-Eskimo cultures inhabited different regions of Greenland. These are defined as: Independence I, Saqqaq, Pre-Dorset, Greenlandic Dorset and Late Dorset cultures. The Palaeo-Eskimo cultures were small scale hunter-gatherers with an extreme specialization in the Arctic world. Within the first half of the 1st millennium AD, two other cultural and ethnic groups arrived in Greenland. These are the Inuit of the Thule Culture, coming into the Thule region, having an origin in Alaska and Siberia, and the Norse people coming into South and Southwest Greenland from Iceland, having a Scandinavian origin. Around c. 1500 AD the only group of people sustaining and thriving in Greenland were the Thule Culture Inuit, while Late Dorset and Norse people had disappeared. The Thule Culture was a hunter-gatherer society that was extremely well adapted to arctic conditions. They had a thriving culture throughout Greenland during the 13th–19th century. During the 16th–18th centuries, increasing contact between Thule Culture Inuit and European whalers/explores were made in West Greenland. This resulted in Inuit migrations towards Disco Bay where much trade was made. With the cooling of the Little Ice Age during the 18th–19th century, the most northern regions of Greenland (Northeast Greenland) are abandoned, while the Thule region was repeatedly re-colonized by Inuit from Canada. In 1721 the European colonization of West Greenland began with the arrival of the priest Hans Egede, and during the following decades Danish colonial trade stations with churches and Danish inhabitants emerged along the West coast of Greenland, attracting permanent Inuit settlements and forming a market and service economy. Today Greenland is a modern self-ruled nation state with a population of Thule Culture origin, as well as of European origin. The prehistory of Greenland is described in this chapter separately for the Thule region, Northeast Greenland and for West, South and East Greenland, because these different regions of Greenland are naturally, topographically and culturally different, and because they have different histories of human occupation.

Introduction to Greenland and Its Human History

The history of human occupation in Greenland has been discontinuous and complex. Greenland is geographically placed as the most eastern island of the Arctic, the nearest land being Ellesmere Island, Canada. The Nares Strait that separates Ellesmere Island and Inglefield Land in the High Arctic Thule region is only 40 km wide, making this most northwestern part of Greenland the “gateway to Greenland” (Gulløv et al.), that is, the natural entrance into the world’s largest island. It is through this area that all indigenous migrations of people to Greenland have arrived, and from here they have occasionally continued into high Arctic Northeast Greenland or down into Western, Southern and Eastern Greenland, populating the low and subarctic regions of Greenland. Greenland is c. 2500 km from south to north comprising three climatic zones (subarctic, low arctic and high arctic) and is characterized by the “inland ice.” The Greenland ice sheet is the second largest glacier in the world covering c. 80% of the island, making only coastal zones and inner fjord inlands inhabitable (see Fig. 1). Greenland can be divided into at least three different biomes with different emigrational history and occupation: The Thule region, Northeast Greenland, and West, South and East Greenland. Each of these areas are separated by specific topographies that are not easily transversed by humans and terrestrial fauna, making them regions with different human settlement histories. Moreover, each of these areas has specific climates, landscapes, icescapes and resources, giving rise to different cultures and economies.

Generally, three different groups of populations have migrated into and occupied Greenland through time: The Palaeo-Eskimo group, the Inuit group and the European group (see Fig. 2). The first was the Palaeo-Eskimo group, from c. 2500 BC–1400 AD, arriving in several migrations through time from Canada, but originating out of the western Arctic, that is, Alaska/Siberia. Archeologically, the Palaeo-Eskimo group in Greenland is defined as five different Palaeo-Eskimo groups depending on their material culture. Through time, these Palaeo-Eskimo cultures populated all parts of coastal Greenland. The Norse group arrived from Iceland and Scandinavia into southwest Greenland c. 900 AD and disappeared c. 1400 AD, occupying only fjords in

Graphics by M. Sørensen.

Fig. 2 Chronology of human habitation of the different regions of Greenland. Graphics by M. Sørensen.

South- and Southwest Greenland (see [Figs. 1 and 2](#)). The Inuit group arrived c. 1200 AD into Greenland via the Thule region, and is the only of these three occupations that has endured to the present day. This group is archeologically defined as the Thule Culture and dated from the 12th century AD until the 18th century AD when the European colonization of Greenland took place (see [Fig. 2](#)). From the 16th century AD and onwards, European explorers and whalers regularly had contact with the Thule culture Inuit of western Greenland, while the Inuit populations of East and most northern Greenland was first encountered by Europeans as late as the 19th and early 20th century. Danish colonization of West Greenland began in 1721 and ended officially in 1953, and has strongly influenced Greenland's society and culture. Today Greenland is an autonomous constituent country of the [Kingdom of Denmark](#). The modern culture of Greenland can be understood as a unique globally influenced hybrid between traditional European and Arctic cultures.

Cultural Preconditions to Live in the Arctic and Arctic Hunter-Gatherer Societies

There are several technological and social inventions that are crucial to sustain life in the most northern biome ever inhabited by humans. High Arctic Greenland is characterized by c. 4 months of winter darkness and 4 months of constant light during summer. The Arctic landscapes and the fauna change radically through the seasons, from a landscape with open sea and modest vegetation to a complete icescape, where sea ice cover ties land and water together, facilitating long distance travel for humans. Clothing, heating, hunting equipment, architecture, logistics, social organization and ideology are among the factors that need sophisticated development in order to survive in these regions. Remarkably, humans developed a life style in which specific knowledge and sophisticated technologies made it possible to live in the high Arctic for the past 4500 years.

The Palaeo-Eskimo People

The Palaeo-Eskimo people were organized in small mobile groups that were able to carry all their goods including tents with a size of 3×4 m in ground plan ([Andreasen, 2003](#); [Odgaard, 2003](#)). This mobile organization enabled this society to exploit resources at particular favorable places, often far apart, during the seasons. The hunting of marine and terrestrial resources is well documented from food remains found in frozen middens and from excavated tent ruins in many areas of Greenland ([Grønnow and Jensen, 2003](#); [Grønnow, 2017](#); [Jensen, 2006](#)) and from excavated tools and weapons that reveal great specialization. At the Qeqertasussuk site at the island of Qeqertasussuk in Disco Bay, well preserved hafted artifacts dating back to the Saqqaq Culture have revealed one of the most sophisticated prehistoric hunter-gatherer tool technologies, consisting of no less than nine hafted compound tool types with specialized use, for example, different lances with foreshafts, harpoons with toggling harpoon heads, atlatl, three-pronged bird darts, bow and arrow ([Grønnow, 2017](#)). Remnants of what is interpreted as boat frames from kayak-like vessels have also been found at the Qeqertasussuk site. The presence of summer camp sites on islands further suggest that the Palaeo-Eskimo people went to sea in simple vessels ([Grønnow, 2017](#)). Saqqaq sites in west Greenland also have evidence of the earliest blubber lamps in the eastern Arctic, made from sandstone and steatite, thus documenting that marine mammal blubber was used as fuel for heat and light as early as 2000 BC ([Grønnow et al., 2014](#)).

The Thule Culture

The Thule culture has been documented archeologically and historically to have been extremely well adapted to the Arctic world, employing much the same toolkit as the Palaeo-Eskimo cultures ([Whitridge, 2016](#)). However, in addition, the Thule culture brought many inventions with them from Beringia, making them the most advanced hunter-gatherer society to have occupied Greenland ([Holtved, 1954](#); [Morrison, 1999](#)). Among these inventions are the umiak, a skin boat up to 10 m long that can carry a large crew. This boat was used for transportation and for large whale hunting. Other advanced equipment included a dry suit made from animal skins. The hunting of large whales and other marine mammals allowed the High Arctic Thule culture to produce food, not only for themselves, but also for sled dogs. The large dog-driven sledge is thus another technology not seen earlier in the Arctic. It provided the Thule culture with superior logistic capabilities. The high seasonal mobility of the Thule culture also affected their architecture ([Whitridge, 2016](#)). In the winter, turf and stone built semisedentary houses were constructed. Supplies could be transported to these lodgings from hunting expeditions or meat caches. During winter journeys, snow houses (igloos) were employed as temporary shelters. During summer, tents of light portable construction were used.

The Thule Region—A Magnet for Prehistoric Migrations

To understand the human history of Greenland it is necessary to address their motivations for making long distance migrations into new lands. More than any other region in Greenland, the Thule region of the northwest holds the key to our understanding of the first migrations. Biologically, the Thule region is characterized by the "North Water polynia" (see [Fig. 1](#)), an open water area between Ellesmere and Ingfield land, formed where sea currents of the polar basin meet upwelling waters from the Atlantic, a process that creates open nutritious waters almost year round, despite extremely low air temperatures ([Schledermann, 1980](#)). The "North Water" is accessible both from the Thule region and from Ellesmere, linking these areas together both biologically and culturally. The North

Water polynia supports a vast marine fauna, including large mammal species such as narwhal, belugas, walrus and bowhead whales. Further, the polynia supports millions of sea birds such as little auks and thick-billed murre. These nest in seaside colonies, fertilizing the land by their guano and thereby creating improved conditions for grasses and a mammal fauna, such as hares, foxes, reindeer and muskoxen (Hastrup et al., 2018). Thus the Thule region is a High Arctic larder of resources that has attracted humans throughout prehistory. Because of this, the Thule region has by far the most complicated human history of Greenland. Prehistoric Arctic hunter-gatherers have frequently passed through this area. Archeological investigations have revealed no less than seven culturally different occupations by Arctic hunter-gatherer societies in the Thule region (Sørensen, 2010, 2012b; Grønnow and Sørensen, 2006; Hastrup et al., 2018). On the other hand, there have also been times when the Thule region appears to have been devoid of human occupation, for example, from around year 200 BC to c. 700 AD (Grønnow and Sørensen, 2006).

The first human occupation of the Thule region, and therefore of Greenland, took place during the middle of the 3rd millennium BC with the arrival of the Saqqaq, the Independence I and the Pre-Dorset cultures (Grønnow and Sørensen, 2006; Sørensen, 2010) (see Fig. 2). Since the 1950s, ancestors to these Early Palaeo-Eskimo groups have been considered the Denbigh Culture in the Bering Strait region, due to resemblances in lithic technology and artifact morphology. This idea has recently been supported with ancient human DNA (aDNA) data, suggesting a Palaeo-Eskimo origin in the Bering Strait region and Siberia (Tackney et al., 2016). The absolute dating of early Palaeo-Eskimo archeological contexts in the Thule region indicates occupations from 2500 to 200 BCE, and again from c. 700–1200 AD. However, a continuous population history cannot be reconstructed for these intervals, because it appears that there were many migrations between Canada and Greenland by different groups with slightly different material culture during this interval. Around c. 800 BCE, a Palaeo-Eskimo group of Late Pre Dorset origin arrived in the region, developing into what is today termed the Greenlandic Dorset. Around c. 200 BCE, this group disappeared, not only from the Thule region but from the whole of Greenland. Thus the island appears to have been devoid of humans for at least 800 years (Jensen, 2016). Around 700 CE, a Late Dorset Palaeo-Eskimo group migrated into the Thule region from low arctic Canada (Appelt et al., 2016) and in the 12th century the Thule culture arrived, subsequently defined as the Ruin Island phase and the Classic Thule culture (Lemoine and Darwent, 2016). It is convincingly argued from excavations in Inglefield Land that the Late Dorset and the Thule Culture people encountered each other, and that they lived in the region concurrently for more than a century (Appelt and Gulløv, 1999, 2009). Moreover, it has been argued from European artifacts found in Late Dorset and Thule culture contexts that Norse people also made their way to the Thule region (Appelt and Gulløv, 2009). The Thule culture people in the Thule region were encountered by Europeans for the first time by John Ross in 1818 at Cape York.

Northeast Greenland—A Vulnerable Place to Live

The region of Northeast Greenland topographically comprises the areas of northern Greenland south to Scoresby Sund Fjord, where the steep 500 km long Blossville coast forms a natural barrier from East Greenland. Northeast Greenland is climatically defined as High Arctic desert, having little precipitation and average summer temperatures below 5°C. Similarly to the Thule region, a number of polynias appear along this coast, driven by sea currents and winds. From a cultural standpoint, the most important of these are the “Northeast water,” the “île-de-France polynia,” the “Sirius water” and the “Scoresby Sund Polynia” (see Fig. 1) (Sørensen and Gulløv, 2012; Sørensen, 2013). The region also is characterized by large inner fjord areas where relatively fertile vegetation and terrestrial mammals can be found (Bennike et al., 2008). The resources of Northeast Greenland are similar to those described for the Thule region. However, the coastal waters are not as nutrient-rich as those along the coasts of West and Northwest Greenland, and the sea mammal populations are therefore generally smaller in Northeast Greenland. Conversely, the terrestrial fauna (reindeer and musk oxen) enjoy better living conditions, but the biological productivity of the region is argued to have been fluctuating through time. This historical phenomenon is also known from other Arctic regions, occasionally making terrestrial resources scarce and prehistoric habitation vulnerable. Substantial archeological and interdisciplinary field work in the region has demonstrated three prehistoric occupations: the Independence I culture, the Greenlandic Dorset culture and the Thule culture (see Fig. 2) (Grønnow and Jensen, 2003; Sørensen and Gulløv, 2012). Further, it has been demonstrated that the archeological remains of these occupations are very often discovered at the very same locations in the vast landscapes of the region, pointing to similar hunting and resource strategies. In other words, a good hunting campsite is a good hunting campsite, regardless of the cultural period.

The history of human occupation of Northeast Greenland is closely linked to the Thule region but it is less complex and far more discontinuous than that of the Thule region. The first migration into the region appeared c. 2500 BCE by Palaeo-Eskimo people, defined as the Independence I culture. The archeologist E. Knuth, who was the first person to uncover Palaeo-Eskimo habitations in the region, defined their migration as the “musk ox way,” due to evidence of musk ox bones in excavated ruins at Peary Land (Knuth, 1967). However, later research has demonstrated that many of the Independence I habitations were actually placed at locations near polynias where there were reliable marine mammal resources. This suggests that the majority of their diet actually was marine. The Independence I occupation of Northeast Greenland lasted not longer than c. 300 years from c. 2400–2100 BCE (Grønnow and Jensen, 2003), based on radiocarbon dating. Thereafter northeast Greenland was devoid of people for around 1300 years, before the second Palaeo-Eskimo migration, the Greenlandic Dorset culture, appeared in the region (Jensen, 2016). Ruins excavated in Pearyland suggest that the Greenlandic Dorset people could have arrived from the Thule region, but as they have a circum-Greenlandic settlement pattern, they may have migrated from East Greenland, instead (Jensen, 2016). The Greenlandic Dorset settlements in Northeast Greenland are mostly found at coastal locations along the northeast coast. At the island Il-de-France, a Greenlandic Dorset site, not less than several hundred settlement structures have been identified, making this site the

largest known Palaeo-Eskimo site ever recorded (Grønnow and Jensen, 2003). Even though these habitations were not all occupied at the same time, they suggest seasonal aggregations of a hitherto unknown size, suggesting a specialized social and economic strategy in Northeast Greenland. It is thought that large marine mammals, for example, walrus or belugas, were hunted corporately here. Similar but smaller Greenlandic Dorset aggregation sites have been found at all the polynias along the coast of Northeast Greenland (Sørensen, 2013). Radiocarbon dating suggests that the Greenlandic Dorset occupation in Northeast Greenland lasted not more than a few hundred years, at most c. 500 years. Afterwards, Northeast Greenland was devoid of human occupation, this time for at least 1600 years. Most of the Greenlandic Dorset settlement structures are identified by their tent rings, often with mid-passage features. However, two other types of habitation structures are also recognized. The first evidence of snow house construction in Greenland is provided by the presence of triangular pavements and “cleaned” circular compressed ground areas with artifacts scatters. Neither of these features have tent rings, hence their interpretation as snow house structures (Sørensen, 2013).

The Thule Culture Inuit arrived in Northeast Greenland c. 1400 AD. That their migration came from the Thule region is well documented by similar artifact morphologies and the diagnostic umiak (an 11 m. long skin boat) with artifact inventory dated to the 15th century, found at Herlufsholm Strand. This site is situated on the most northeastern coast of Peary Land (Knuth, 1980). The Thule culture in Northeast Greenland developed particular cultural characteristics, for example, a harpoon shaft with proximal wings, flat harpoon heads and house architecture with recesses in the front wall (Sørensen and Gulløv, 2012). It is argued that these characteristic material traits were borrowed or inspired not only from the Thule culture in Thule but also from the Punuk culture of Alaska and from the late Dorset culture (Gulløv, 2004:311). The Thule culture winter habitation clusters in the southern area of the region have often been found on southern coastal slopes. Large habitation sites were particularly placed near where large marine mammals are known to gather for example, the Sirius polynia and the Scoresby sund polynia. However, many smaller settlements have also been found in the inner fjords where ringed seals can be caught on the fast ice and terrestrial mammals are known to appear (Gotfredsen, 2010). Similar to what was seen in the Palaeo-Eskimo culture, the importance of the polynias is paramount to the Thule Culture. At the 2 km long Walrus Island in the Greenlandic Sea, 118 temporary Thule culture tent foundations, 70 stone build shelter constructions, 479 small stone build caches (size of a seal), 459 large caches (size of walrus or larger), and several large aggregation structures from communal hunting have been recorded at the hostile boulder field terraces (Grønnow et al., 2011) (see Fig. 1). A similar site with numerous caches is located at Scoresby Land near the Scoresby Sund polynia (Sandell and Sandell, 1991). The Walrus site and other polynia sites show that a key strategy for the people of the regional Thule Culture was to hunt and create a surplus of food and fuel from large marine mammals, that is, walrus, large seals and whales, at particular favorable hunting sites close to the recurrent polynias. The Thule Culture diet in prehistoric Greenland has been investigated by faunal analysis and isotopic studies of human bones. The results show that the diet in Northeast Greenland was more terrestrial-based than in any other region of Greenland (Gulløv, 2012).

During the 19th century the Inuit population of the region gradually decreased and it contracted in the southern Scoresby Sund area before it finally disappeared (Sørensen and Gulløv, 2012). It is unknown why the population disappeared, but small scale migrations have been documented south into East Greenland, suggesting that at least some people left the area. Other arguments focus on the cooling of the little ice age (LIA), that made living conditions unfavorable in the region. Another suggestion is that European large whale hunting in the Greenland sea during the 17th century diminished the whale population to such degree that this food resource disappeared from Northeast Greenland. The cause of the regional abandonment remains unknown, yet these peoples' living for almost 500 years as an isolated population in a High Arctic environment, considering the vulnerability of such a population, is a remarkable achievement.

West, South and East Greenland—The Land of Plenty and of Cultural Encounters

West and South Greenland comprises the most fertile regions of Greenland and has the most continuous human habitation history. From north to south the climate zones are arctic and subarctic. The regions are characterized by coasts, fjords, large islands and archipelagos with diverse and abundant marine resources and a rich avian fauna. However, Central West Greenland also holds Greenland's largest unglaciated inland areas, where herds of reindeer are numerous, even today.

Probably the most important regional archeological site is the Sermermiut site in Disco Bay, where stratigraphy reveals occupations of Saqqaq, Greenlandic Dorset and Thule Cultures up to historical times (see Fig. 1) (Larsen and Meldgaard, 1958). Saqqaq sites with permafrozen middens have been excavated (see above) at Disco Bay, and these middens have also yielded the first human remains from Greenland: a lump of hair from a human male. The hair was DNA-sequenced, revealing genetic similarities to modern populations from the Bering Strait region (Rasmussen et al., 2010). This strengthens the archeological interpretation that human migrants from the Bering region were the first pioneers in Greenland. The Saqqaq people populated and traveled along all parts of the coasts in West and South Greenland. From an archeological perspective, they employed a very conservative and static lithic technology during their entire habitation, in which a large number of carefully manufactured, primarily bifacial lithic tool types, were produced. These were manufactured by means of direct soft techniques, pressure tool technique and grinding. The conservative nature of the technology also included the choice of lithic raw materials chosen for lithic tools. Burins, adzes and bifacial tools were generally made from dark, tough, silicified slates and schist, while scrapers and pressure blades were generally made from fine grained microcrystalline quartz such as agates, chalcedony and rock crystal (Sørensen, 2012b). In West Greenland, a particular lithic raw material source, located at the “Nuussuaq” peninsula north of Disco Bay, was systematically employed, at least up to 800 km from its outcrop. This raw material is a metamorphosed slate termed “killiaq.” The primary use

of this raw material suggests that Saqqaq society, at least in some periods, had a social network through which they regularly traded over very long distances (Jensen, 2006; Sørensen, 2012b).

The main prey taken by people of the Saqqaq Culture was the same as all the other of hunter-gatherer societies of the Eastern Arctic: marine fauna and especially seals. This has been documented from preserved faunal materials at sites with organic preservation (Meldgaard, 2004), and also inferred from the fact that their settlement locations most often are found in landscapes with good access to seals. However, inner fjord and inland sites with remains of preserved reindeer bone demonstrate that inland hunting, probably conducted by bow and arrow, was part of their economy (Grønnow et al., 1983). The dating of the Saqqaq culture reveals that they existed in the regions from c. 2400–800 BCE, that is, about 1600 years. From radiocarbon dating and regional analysis there is evidence that the Saqqaq Culture left the rich Disco Bay area, and possibly also areas in south and east Greenland, to relocate in central West Greenland (Jensen, 2006), where the youngest occupation dates occur at the Nipisat site in the Sisimiut area (Gotfredsen and Møbjerg, 2004). Around c 800 BCE, evidence for the Saqqaq culture disappeared completely. Yet, at the same time a group of Early Dorset, deriving from the Predorset Culture in Canada, arrived in the Thule region and down into West Greenland. This Dorset group, formerly termed the Independence II or the Dorset 1 culture, is now termed the Greenlandic Dorset. It represents the second cultural habitation of West Greenland, and it is possible that this Dorset culture encountered the very last people of the Saqqaq culture in central West Greenland (Jensen, 2016). The Greenlandic Dorset Culture employed many of the same coastal settlement sites that were used by the Saqqaq people, while evidence for inland occupation is scarce (Jensen, 2006). Their lithic technology comprises many of the same methods and techniques seen in the early Palaeo-Eskimo cultures. However, there are also significant differences in their technology. Their raw material choice was more flexible and generally without long distance import; they did not produce arrow heads and drills, they produced many micro blades of high quality, and the shape of their bifacial tools is different (Sørensen, 2012b). Radiocarbon dating shows that the Greenlandic Dorset people lived in West Greenland for around 800 years. Around the year 1 AD, they disappeared completely and the region seemingly became unoccupied for around c. 1000 years.

The Norse people of Scandinavian and European origin next settled West Greenland, and more particularly in the fjords of South Greenland and in the Inner Nuuk fjord in West Greenland (Arneborg, 2008). From radiocarbon dating and Saqa literature it can be deduced that they must have arrived c. 985 AD, and that they initially migrated from Iceland. Unlike any earlier people in Greenland, the Norse people were farmers, employing land for agriculture, primarily pasture for cows and sheep. The Norse were part of a North Atlantic European society, and they maintained regularly contact with Europe throughout their Greenland occupation. A key technology that enabled the Norse people to sail to Greenland was their clinker-built sea going long ships with square sails. With these vessels they were able to maintain contact with Europe and make expeditions to other parts of Greenland as well as to North America. An important trade ware was walrus tusk that the Norse exported to Europe, replacing elephant tusk which was not available in Europe during the early middle ages (Dugmore et al., 2007). The Norse disappeared from Greenland in the 15th century. It is not known why they abandoned Greenland, but the cooling of “the little ice age” made their pastoral lifestyle untenable. There was also a general contraction of the North Atlantic societies due to the Black Death. These two explanations are considered the most likely.

Around 200 years after the Norse arrived in Southwest Greenland the Inuit of the Thule Culture arrived in West Greenland from the Thule region (see Fig. 2) (c. 1200 AD). There are no signs of Inuit settlements in the fjords and regions where the Norse lived during their stay in Greenland (Gulløv, 2007, 2008). Thus, the archeological material as well as the saqa literature provide no evidence that Inuit and Norse people had strong relations in Southwest Greenland. On the contrary, their possible few encounters seems to have been hostile. The Inuit traveled all around Greenland and inhabited most coastal fjords and areas with their mobile lifestyle, except those of the Norse, until after the 15th century.

During the 16th and 17th century European explorers and whalers had regular contact with Inuit people. During the 17th and the first part of the 18th century, whalers, especially Dutch whalers, traded regularly and annually with the Inuit at Disco Bay (Gulløv, 2016). Based on historical sources and archeological material, this trade with Europeans was very attractive to the Inuit. The Dutch trade initiated Inuit seasonal journeys from South and East Greenland to Disco Bay. This activity lasted several years. One of the major changes in Inuit life and society, the communal long house, was introduced in this period. It is argued that this architectural innovation was a consequence of the trade journeys, reflecting the large size of the journeying groups (Gulløv, 1997). Thus, while the cooling of the little ice age probably was a great disadvantage to Norse farmers, it seems not to have had negative impacts on Inuit hunting societies living in the same environments that the Norse abandoned (Sørensen, 2012a). This paradox cannot be explained simply by the difference in economies, as the Norse were able to catch many marine species, and they did so increasingly during their occupation of Greenland (Arneborg et al., 2012). Culture and identity are important parameters to any people and society, and the fact that the Norse people lost trading and contact to Europe, and probably could not proceed as successfully with pasturing livestock, must have seriously endangered their identity and existence as Norse people.

With the Danish colonization of Greenland the history of Greenland, and particularly West Greenland, completely changed. The colonization started in 1721 and was led by the priest Hans Egede. A network of colonial trade stations and churches was established along the coasts of West Greenland where seagoing vessels could enter. As a consequence, the Inuit increasingly made permanent settlements at the trade stations during the 18th century, and thereby lost their traditional mobility and their economic independence. Christianization increasingly changed their traditional societal structure and religion. With the colonization of Greenland, people became dependent on imported food and most other materials as they adopted the European lifestyle. Thus, even though the biomes of Greenland have endured almost intact through the history of human habitation, the delicate interplay and human dependency on the sea and land and its resources have become increasingly altered since Danish

colonization. Today traditional hunting is foremost a hobby to most Greenlanders and only in the Thule region and few other places in West and East Greenland are some people still living from full time hunting. Greenland is today a modern nation and state with c. 56,000 inhabitants and a strong national identity.

Abstract

Antarctica is the coldest, driest, windiest, and highest continent in the world. The harsh conditions of this remote continent are a major challenge for all species which inhabit these areas. Inland elevated areas of the Antarctic Plateau present extreme cold and dry conditions. Coastal areas of the continent are milder; however, they are subjected to strong katabatic winds flowing from the plateau. Climate conditions over the Antarctic Peninsula are less severe and wet which support well-developed plant communities including vascular plants. West Antarctica is now undergoing great changes, the large warming occurred in the second half of the 20th century and the basal melting produced by the intrusion of relatively warm ocean water are driving an unprecedented ice retreat and new ice-free areas are emerging, providing new opportunities and challenges for Antarctic biota. This will ultimately result in changes of coastal Antarctic ecosystems.

Physical Geography

Antarctica is the southernmost continent in the world and it is centered asymmetrically around the geographic South Pole and surrounded by the Southern Ocean (Fig. 1). Its entire territory covers an area of 14 million km² that lies south of 60°S of which only a 0.3% is deglaciated. Almost the whole continent is covered by an enormous ice sheet that contains more than 26×10^6 km³ of ice, an amount equivalent to about 58 m of sea-level rise (Fretwell et al., 2013). The ice sheet has an average thickness of about 2.1 km, making Antarctica the highest continent in the world. The continent is geographically divided into two by the Transantarctic Mountains: East Antarctica and West Antarctica. East Antarctica is a wide and high territory with semicircular shape that is almost totally within the Eastern Hemisphere. West Antarctica is smaller than East Antarctica in height and extension and is irregularly shaped. Its northernmost tip ends with a large peninsula called the Antarctic Peninsula. Hereafter West Antarctica and Antarctic Peninsula will be discussed separately.

On both sides of West Antarctica lie two massive floating platforms of ice called the Ross Ice Shelf and the Filchner-Rone Ice Shelf. These extend from grounded glaciers on land and flow down onto the ocean. Ice shelves range from 100 to 1000 m thick and there are many more smaller ones surrounding most of the Antarctic coasts. Unlike ice shelves, sea ice is thinner, only few meters thick. When the sea surface freezes in winter, the continent doubles its extension (Fig. 2). On its maximum extension in September, sea ice extent covers almost all of the sea area south of 60°S. Sea ice cover has a seasonal regime. Antarctic sea ice is almost totally melted in summer, reaching its minimum extent in February. Consequently, unlike Arctic sea ice, the Southern Ocean is mostly covered in winter by only first-year ice that is less than 1 m thick.

Large-Scale Circulation

Radiative balance in Antarctica is negative. This is produced because outgoing longwave radiation is uncompensated by incoming shortwave radiation. In Antarctica, annually averaged shortwave radiation incomes are low, owing to the large solar zenith angles and the high albedo of the snow cover. Despite the cold surface, outgoing longwave radiation at the top of atmosphere is relatively large due to the dry polar atmosphere. The resulting negative radiation budget should be restored by a poleward energy flux. The ultimate consequence of the large-scale circulation of the oceans and the atmosphere is the poleward transfer of heat that restores the energy budget.

The Southern Ocean is connected with the major oceans of the planet and plays an important role in Earth's climate system. The most dominant feature of the Southern Ocean is the Antarctic Circumpolar Current that flows eastward around Antarctica due to the momentum applied by the strong westerly winds. Westerlies also induce a northward Ekman transport near the surface of the Southern Ocean. Following this movement, cold Antarctic water in the south meets and sinks under the relatively warmer Subantarctic water at the Antarctic Convergence. Annually averaged, meridional heat transport contribution by overturning circulation is directed northward while horizontal gyres and transient eddies of the Southern Ocean contribute to the southward meridional heat transport (Spence et al., 2012). The total contribution of the Southern Ocean to the meridional heat transport is directed southward; nonetheless, most of the poleward heat transfer in the southern high latitudes is led by the atmosphere (Trenberth and Caron, 2001).

The Antarctic continent is centered approximately inside the thermally direct atmospheric polar cell of the tricellular large-scale atmospheric circulation system. Therefore, cold air subsides over the continent by gravity and flows near the surface to lower latitudes while turning to the west due to the Coriolis force caused by Earth's rotation. Around the continent, cold continental air converges with the temperate marine air, creating a strong horizontal thermal gradient that develops several low-pressure areas around the continent where the air is able to uplift to the high troposphere. In order to restore the air drained to the north on the surface, the air risen at the polar front flows back aloft to the pole, closing the loop of polar circulation. Through this process, the atmosphere effectively transports heat to the pole and balances the net radiative loss of heat of the continent.

The ring of low-pressure systems that encircle the Antarctic continent from 60°S to 70°S is known as the Antarctic circumpolar trough (Jones and Simmonds, 1993). It is one of the most active cyclonic areas of the world. On any day, the Antarctic continent is surrounded by several cyclones (Fig. 3). As the low-pressure systems turn clockwise in the Southern Hemisphere, there is a climatological belt of westerlies north of the circumpolar trough and easterlies south of it. Cyclones generally track eastward with a small southward component over the Southern Ocean off the Antarctic coast. Often, cyclones turn to the south where they provide relatively warm and moist air and precipitation, but they can barely penetrate onto the plateau, except on very rare occasions. The Antarctic circumpolar trough is not zonally symmetric, but it has a climatological wave number 3 pattern. That is, the circulation makes three waves around the South Pole, with the cyclonic centers close to 30°E, 100°E, and 150°W (Fig. 4A). The latter is known as the Amundsen-Bellinghousen Seas low, and is the most pronounced. The meridional temperature gradient has two maxima around the equinoxes. Because of this, the Antarctic circumpolar trough contracts and deepens southward in spring and autumn and weakens and displaces northward in summer and winter in a movement known as Semi-Annual Oscillation that affects the whole atmospheric circulation of the continent (van Loon, 1967).

In addition to the synoptic-scale cyclones, mesoscale cyclones are frequent over the Southern Ocean. Mesoscale cyclones, also called polar lows, are defined as cyclones with less than 1000 km diameter and a lifetime shorter than 24 h (Rasmussen and Turner, 2003), but satellite imagery has shown that most of them have a horizontal diameter less than 500 km and may exist in a wide range

of time scales, from few hours to several days. Despite their small size and short life, mesoscale cyclones have an appreciable influence over the Antarctic coasts, due to their high wind speeds and associated increased precipitation. Climatologically, in the Southern Hemisphere their maximum density is located at 5–10° north of the Antarctic sea ice, with maxima over the Amundsen and Bellingshausen Seas and off the coast of Wilkes Land (Irving et al., 2010). Their maximum activity is in autumn while the lowest activity has been observed in spring (Irving et al., 2010).

Climatic Regions in Antarctica

Overview of the Climate of Antarctica

Antarctica is the coldest, windiest, and driest place on Earth. Those conditions are the result of the continent's location and height. Most of Antarctica is characterized by a polar climate (category ET) in the Köppen climate classification, except for some coastal areas of the Peninsula that have a tundra climate (category EF) that is, at least a month with an average temperature above 0°C.

Mean annual temperature in Antarctica decreases with latitude, due to the angle of incidence of the solar radiation on the Earth's surface. Of course, the temperature also decreases with altitude. This means that the coastal regions of the Antarctic Peninsula are the warmest areas and the high ice domes of East Antarctica are the coldest places of the continent (Fig. 4B). The high surface albedo of the ice and the radiative cooling of the continent also contribute to the low temperatures of the inner lands.

Indeed, winds over the continent are highly influenced by the radiative cooling of the ice cover. The air, very cold and dense, drains downslope by gravity, enclosed in a layer <1000 m thick with the maxima between 100 and 200 m (Parish and Bromwich, 2007). These winds are known as katabatic winds and they overlap and dominate over the polar cell described in "Large-Scale Circulation" section (Fig. 5). Katabatic winds are weak over the domes and flow perpendicular to the height levels and increase with slope angle, blowing hard and rather constantly over the coastal areas, especially in winter (Fig. 4C). By contrast, winds over the Antarctic Peninsula and Southern Ocean are dominated by the mobile cyclones as they pass over the area, and when wind directions are averaged, they tend to come from the west and northwest.

Often it is hard to identify clouds in Antarctica, either because of blowing snow, very thin cirrus cloud cover, or the absence of daylight in winter. Satellite imagery provides no better solution, due to the similarity of the bright temperatures of the snow and clouds. However, the combination of observational, satellite studies and computer simulations has been able to discern the cloud structure of the continent. The western side of the Antarctic Peninsula and the continental coast are extremely cloudy areas throughout the year with dominant low stratiform clouds and fog. Conversely, cloudiness is scant in the inner plateau and dominated by thin cirrus clouds that do not obscure the sky.

Precipitation is also difficult to measure in Antarctica because it falls mainly in form of snow that is prone to be deflected by the wind as it falls into precipitation gauges. Measurements of snow on the ground are also unreliable because the snow is often redistributed by wind after falling. Nonetheless, recent precipitation measurements indicate that mean annual precipitation derived from reanalysis is a reliable estimate (Palerm et al., 2017). The corrected estimates indicate that precipitation is abundant in the coastal areas but is scarce over the plateau, which is essentially a frozen desert (Fig. 4D).

Fig. 5 Annually averaged surface wind streamlines over Antarctica from ERA Interim. Width and color represent the mean wind speed.

Due the homogeneity of the continent, the climate of Antarctica is very uniform. Nonetheless it is worth to classify the climate of Antarctica into three different regions: peninsula, continental coast, and continental plateau, each of which exhibits special features.

Antarctic Peninsula

The Antarctic Peninsula (AP) is the wettest and the mildest area of Antarctica and it is broadly located outside the Antarctic polar circle. Its climate is known as maritime Antarctic and it is able to support well-developed moss and lichen communities, liverworts, and the only two Antarctic species of vascular plants. The vegetation grows in the relatively abundant deglaciated areas (Longton, 1967). Different kinds of marine mammals and sea birds and few insect species live on the coasts. Unlike the rest of the continent, it has a very complex orography and many small islands. Almost all the territory is located near to the sea. The sea provides a moisture source to the area, and when it is not covered by ice, the difference between day and night temperatures becomes reduced. However, the mountain range orientated in the north–south direction, perpendicular to the prevailing westerlies, causes a sharp variation in weather conditions between the western and eastern side (WAP and EAP) of the AP. A third region subjected to little different conditions is the South Shetland and South Orkney Islands, located in the Southern Ocean at the northern tip of the AP.

AP localities near the sea are characterized by having several months with mean temperature above 0°C in summer. In particular, summer temperatures exceed 0°C on the Southern Ocean islands for 3–4 months of the year (see Bellingshausen in Fig. 6A), at WAP for 2–3 months (see Faraday/Vernadsky in Fig. 6B) and at EAP for 1–2 months (see Esperanza in Fig. 6C).

Fig. 6 Monthly Surface Air Temperature at different stations with their location in parentheses. SSI: South Shetland Islands, WAP: West Antarctic Peninsula, NEAP: North-East Antarctic Peninsula, EAC: East Antarctic Coast, IS-WAC: Ice Sheet—West Antarctic Coast, WP: Western Plateau, EP: Eastern Plateau. Source for the data used in creating the figure: RADER station surface data Turner, J., Colwell, S.R., Marshall, G.J., Lachlan-Cope, T.A., Carleton, A.M., Jones, P.D., Lagun, V., Reid, P.A., Iagovkina, S., 2004. The SCAR RADER project: Toward a high-quality database of mean Antarctic meteorological observations. *Journal of Climate* 17, 2890–2898. doi:10.1175/1520-0442(2004)017<2890:TSRPTA>2.0.CO;2.

variation is less than 10°C on the Southern Ocean Islands with winter mean temperatures between −5 and −10°C. Farther south at the WAP, annual thermal variation increases because of the region's isolation from moisture sources, caused by sea ice cover in winter. But it is on the EAP where winter temperatures are colder, due to the even further isolation from moisture sources, caused by the mountain range, the Larsen Ice Shelf, and the often-iced Weddell Sea. In this area, mean annual temperature variation exceeds 15°C. Throughout the AP, temperatures may present sharp variations due to the cyclonic conditions, as polar front waves progress, and warm or cold air is advected. On any given day, even in winter, temperatures may reach 0°C.

Wind speeds at the AP vary widely as they are associated with the frequent cyclones that cross the area. However, when their direction is averaged, the AP is subject to climatological westerly winds associated with the circumpolar trough. Westerlies have a seasonal behavior due to the Semi-Annual Oscillation, being stronger at the equinoxes and weaker at the solstices, when the circumpolar trough contracts (equinoxes) or extends (solstices) (van den Broeke, 1998; van Loon, 1967). Westerlies are often blocked by the AP mountain range, but when they have sufficient velocity to overtake the barrier they lose their moisture on the windward side of the range and flow dry and warm downslope on the leeward side (Parish, 1983). These winds are known as foehn winds, and play a crucial role on the surface melting of the EAP ice shelf (Elvidge et al., 2015). When winds flow from the east, the damming up of cold stable air against the mountain ranges creates strong northward winds that run parallel to the mountains on the EAP (Parish, 1983).

The AP is a very cloudy area, especially over the islands and on the western side, where mean cloud cover is over 80% in any month. As moisture coming from the west is released on the windward side of the mountain range, cloudiness decreases sharply in the EAP. At the moment, reliable precipitation measurements are not yet available for the Antarctic Peninsula. However, model reanalysis and satellite data suggest that precipitation may exceed 800 mm year^{−1} in many places on the WAP (Palerm et al., 2014). Precipitation is also greater on the Southern Ocean islands, especially those with high mountains. Conversely, precipitation decreases sharply on the EAP, due to the moisture blocking of the AP mountains. Autumn is the wettest season because of the contraction of the circumpolar trough, and therefore the increase of the cyclonic conditions coincides with moisture sources of the still-open seas. In summer, much precipitation over the AP falls as rain.

Continental Coast and Ice Shelves

The low lands and ice shelves of the rest of the continent are influenced both by inland dry and cold air and by the more temperate and moist air from the Southern Ocean. At East Antarctica and some parts of West Antarctica, the ice sheet rises in elevation relatively quickly, roughly at 200 km inland of the coast. In contrast to this, the large flat and low Ross and Filchner-Ronne ice shelves extend hundreds of kilometers inland. Except for small ice-free areas called the Antarctic oasis, most of the coast is covered by glacier ice or ice shelves. On some of these ice-free areas moss and lichen communities may be found. The major ice-free area of the continent is the McMurdo dry valleys, on the west side of the Ross ice shelf. These valleys constitute a cold dry desert of about 4500 km² (Fountain et al., 2010).

Mean temperatures at the East Antarctic coast are higher than those of the West Antarctic coast located further south. Temperatures at all the research stations situated on the eastern coast share similar temperature records (here Mawson is plotted in Fig. 6D). At these stations, mean monthly temperatures may exceed 0°C in December or January when open waters are close to the coast. In winter, mean temperature remains above −20°C. At the southern coasts of West Antarctica and the Ross and Filchner-Ronne ice shelves (see McMurdo in Fig. 6E), summer mean temperatures are about −5°C and winter temperatures fall between −25°C and −45°C. During winter, the temperature over the inland ice sheets may fall below −60°C (Costanza et al., 2016). Research stations at the continental coast, as well as those over the plateau, experience a coreless winter (van Loon, 1967), that is, temperature decreases quickly in autumn and remains almost constant throughout the winter. This is produced by different causes, among which is constant radiational forcing during the dark season enhanced by the low heat conductivity of the snow and circulation changes.

All the Antarctic coast experiences katabatic winds descending from the plateau (Fig. 5). Those winds are very constant in direction and very strong (Parish and Bromwich, 2007). They usually reach the maximum velocity at 200 km inland and then slowly decelerate by friction along most of the coast. Katabatic winds are persistent, stronger in winter than in summer, and can blow over 10 ms^{−1} for weeks. The katabatic regime at the coast is modulated by the surrounding cyclones, being suppressed by southward cyclonic winds, and enhanced by northward cyclonic winds, as lows approach, or move away, respectively (Parish and Bromwich, 1998). Cape Denison, near Dumont d'Urville, is believed to be the windiest place in the world with mean annual winds around 20 ms^{−1} (72 km/h) (Wendler et al., 1997). Once the wind reaches the coast it suffers a hydraulic jump, sharply decreasing its velocity offshore. Katabatic discharge also helps in creating conditions to generate mesocyclones on the Antarctic coasts. Katabatic flow also produces barrier winds at the Transantarctic Mountains side of the Ross ice shelf when statically stable air interacts with the mountain range (Costanza et al., 2016; Parish et al., 2006).

Clouds are frequent over coastal areas and are often associated with synoptic-scale weather systems. Cloudiness varies little with the seasons. Moisture sources for cloud or fog formation and precipitation in summer come from the near-to-the-coast open sea. However, in winter the ice edge is far away from the coast. Nonetheless, the action of katabatic winds on the sea ice generate unfrozen areas next to the coast, called polynyas (Bromwich and Kurtz, 1984); these open water areas may provide moisture to sustain winter clouds and precipitation. Snowfall measurements indicate that precipitation on the East Antarctic coast averages between 300 and 900 mm year^{−1} (Souverein et al., 2018). Precipitation aloft is higher but most of it is sublimated by the strong katabatic winds (Grazioli et al., 2017). Precipitation levels are not evenly distributed along all the coastal areas; there are preferential

areas. Coastal zones located east of the climatological lows in such locations as Enderby and Wilkes land, where northern winds are more common, receive more precipitation than those coasts located further west, such as Dronning Maud and Princess Elizabeth lands, which are more prone to have southerlies due the position of the cyclonic centers of the circumpolar Antarctic trough (Bromwich, 1988). Most of the precipitation falling on the East Antarctic coast occurs in a few large events. These storms account for more than 70% of annual precipitation and are associated with atmospheric rivers (Gorodetskaya et al., 2014).

Antarctic Plateau

Antarctic plateau is the coldest place on Earth. It consists of an elevated, ice-covered desert located in the inner continent. The terrain is flat and homogeneous, with slight negative slopes that increase from the high interior to the coast. Two differentiated regions can be distinguished: the relatively small and low West Antarctic plateau and the higher and wider East Antarctic plateau. These two regions are divided by the Transantarctic Mountains. The East Antarctic plateau has three high altitude domes with elevations of 3810 m (Dome F), 3233 m (Dome C), and 4093 m (Dome A), from north to south respectively. The geographic South Pole is located on the East Antarctic ice sheet, but near the boundary with the West.

Mean annual temperatures on the Antarctic ice sheet vary with altitude. Thus, the West Antarctic Plateau (see Byrd in Fig. 6F) experiences warmer temperatures than the East Antarctic Plateau (see Amundsen-Scott in Fig. 6G and Vostok in Fig. 6H). Because the West Antarctic plateau is lower in elevation than the East Antarctic plateau, the former is more prone to intrusions of marine warm and moist air than the latter. Coreless winter conditions are more pronounced here than in coastal areas, where even a winter temperature reverse may occur in May or June (Thompson, 1969). Summer mean monthly temperatures reach -10 to -15°C at Byrd Station; they average -25 to -30°C at Amundsen-Scott Station, and -30 to -35°C at Vostok. From March to September, mean temperatures fall to -25 to -40°C , -50 to -65°C , and -60 to -70°C , at Byrd, Amundsen-Scott and Vostok stations, respectively. The lowest near-surface air temperature on Earth was recorded in Vostok, with -89.2°C (Turner et al., 2009).

The Antarctic Plateau wind field is dominated by katabatic winds constrained in direction and speed by topography (Fig. 5). They are generally calm over the Antarctic Domes and flow downward perpendicular to the height level and accelerating with slope. Wind fields have a seasonal variability, being slower from December to February than in winter months (Parish and Bromwich, 2007). The net northward air mass flux is restored by a broad scale subsidence owing to the polar cell.

Over the Antarctic Plateau there is a fine veil of ice crystal clouds (cirrus). These clouds are semitransparent, and almost perpetually cover the sky. This makes it difficult to determine whether the sky is cloudy or clear (Turner and Pendlebury, 2004). The Antarctic Ice Sheet is one of the driest areas of the world. Absolute humidity is low because the maximum moisture content of the air decreases with temperature. Precipitation here is scarce and often falls as diamond dust, that is, small ice crystals falling from clear or nearly clear cirrus skies (Turner and Pendlebury, 2004). Snow is quickly redistributed by the wind after falling to the ground.

Climate Change, Ozone Depletion, and Modes of Variability in the Southern Hemisphere

Since the 1970s, climate change over the Southern Hemisphere has been characterized by the radiative cooling of the stratosphere, owing to ozone depletion caused by anthropogenic emissions of chlorofluorocarbons (Solomon, 1999). The ozone reduction over Antarctica is much larger in the southern spring, when approximately half of the total stratospheric ozone over Antarctica declines sharply, producing the well-known ozone hole. As a result, circulation patterns in the lower stratosphere and troposphere have experienced several changes such as a reinforcement of the westerly winds and the poleward movement of the southern polar jet, modifying the climate modes of variability of the Southern Hemisphere (Bandoro et al., 2014).

Climate modes of variability are spatial patterns in which most climate variance can be explained by temporal variations. There are several modes of regional variability around the world but there are two that specially affect the Antarctic climate: the Southern Annular Mode (SAM) and El Niño Southern Oscillation (ENSO):

- SAM is the principal mode of atmospheric variability in the nontropical Southern Hemisphere and it causes large impacts on Antarctic climate (Marshall, 2003). Broadly speaking, SAM represents the zonally averaged latitudinal gradient of pressure, and it controls the latitudinal position of the midlatitude jet. When SAM is positive, pressure is anomalously high over Antarctica and low at the mid-latitudes. When SAM is negative, pressure is anomalously low over Antarctica and high at the mid-latitudes. Positive SAM is associated with the contraction and intensification of the circumpolar westerly wind belt and the poleward shift of the cyclone track. This is linked to warming in the Antarctic Peninsula and cooling in the rest of the continent. The disturbance in the ocean circulation linked to the SAM-related wind patterns may affect regional sea-ice extent (Lefebvre et al., 2004).
- ENSO explains the interannual variability of the equatorial Walker circulation. During the warm phase of ENSO (El Niño Southern Oscillation), the Walker cell weakens or reverses, resulting in a very little upwelling of cold water in the eastern equatorial Pacific and warmer than average ocean temperatures. In the cold phase (La Niña), the Walker cell strengthens and the ocean cools. Tropical convection related to ENSO, together with other factors, such as the zonally asymmetric structure of the SAM, produces a tropospheric wave train that strengthens the Amundsen-Bellingshausen Seas Low during the ENSO cold phase and weakens it during the ENSO warm phase. This strongly affects the climate of the Antarctic Peninsula and the Ross sector of the continent (Fogt and Bromwich, 2006).

Temperatures over different research stations throughout Antarctica show large annual variability as they are very sensitive to the different climate modes of SAM and ENSO, and the position of the Amundsen-Bellinghousen Seas Low (Hosking et al., 2013). In summer, temperatures in coastal areas show weak variability due to the damping effect of the open water (Monaghan et al., 2008). This contrasts with the high variability of the temperatures recorded during the cold season in coastal areas. These temperatures are highly dependent on the extent of sea ice cover and the proximity of open water (including the formation of polynyas). Regional ocean circulation and air-sea-ice feedbacks also play key roles and contribute to increasing temperature variability of the continent.

Temperatures over the Antarctic Peninsula also show long-term natural variability, that is large persistent cooling or warming trends consistent with natural variability. Still, this area has undergone a large warming since mid-20th century, with a linear trend over $+0.3^{\circ}\text{C}/\text{decade}$ followed by a slight cooling during the first years of the 21st century (Gonzalez and Fortunyn, 2018). 20th century warming is linked to regional changes in troposphere circulation, due to the increase of northerly winds and cyclonic conditions. These changes are caused by the shift in position and strength of Amundsen-Bellinghousen Seas Low and the positive trend of the Southern Annular Mode in response to greenhouse gases increasing and stratospheric ozone depletion (Marshall, 2007; Raphael et al., 2016). Those changes also yield to an unprecedented warming over the West Antarctic region during the second half of the 20th century. This region is one of the most rapidly warming places of the world (Vaughan et al., 2003). Conversely, East Antarctica has not shown any warming during this period. Actually, this region exhibited a slight cooling trend since 1958 that may be attributed to internal climate variability (Smith and Polvani, 2017), atmospheric circulation changes related to ENSO (Clem et al., 2017) or to the recently discovered negative greenhouse effect (Schmithüsen et al., 2015).

Antarctic Future

Recent satellite measurements showed that the Antarctic ice sheet is losing ice and that the rate of ice loss is increasing (Shepherd et al., 2018). Ice loss is uneven over the continent; while East Antarctica may slightly gain some ice, the Antarctic Peninsula and especially West Antarctica ice sheets are thinning quickly. Most of the ice sheets are confined by ice shelves near the sea. If these shelves collapse, ice sheet thinning would rapidly increase the rate of ice loss. The southern progression of the summer 0°C isotherm is contributing to ice sheet retreat in the Antarctic Peninsula, occasionally leading to catastrophic breakup due to hydrofracturing driven by surface melting such as Larsen B collapse in 2002 (van den Broeke, 2005). However, surface temperature is not the main driver of West Antarctic ice sheet thinning. Here, most of the thinning is in the bottom of the ice shelves due to the basal melting produced by the intrusion of relatively warm ocean water into subshelf cavities (Shepherd et al., 2018). This results in the retreat of ice sheet grounding lines and in reduced basal traction, both of which speed up the thinning process. The rate of deep-water intrusion is controlled by wind stress and direction on the surface.

Climate projections predict a rapid retreat of the Antarctic Peninsula and West Antarctic ice sheets in the near future (DeConto and Pollard, 2016). Certainly, over the next century, large extensions of new Antarctic ice-free areas will emerge, most of them on the Antarctic Peninsula. Many islands may also become totally ice-free. This will result in new habitats and opportunities for both native or invasive biota, and an increase of connectivity (Lee et al., 2017). The most catastrophic scenario would be the collapse of the West Antarctic Ice Sheet. This may occur in the next centuries (DeConto and Pollard, 2016). This scenario would also produce regional changes in atmospheric circulation, along with a 4.8 m rise in global sea level.

Abstract

The Antarctic terrestrial biome includes terrestrial vegetation communities and inland aquatic ecosystems of lakes and streams. Its formation relates to the history of the southern supercontinent Gondwana. Before the split of Gondwana and the separation of continents, the Antarctica played an important role as a bridge facilitating the spread of terrestrial ecosystems from South America to Australia and New Zealand. Upon the formation of the Drake Passage, ca. 30–50 million years ago, Antarctica started to cool down and its terrestrial ecosystems mostly perished. Its modern ecosystems are quite simple and harbor limited biodiversity. The ecosystems feature a significant role of prokaryotes, cryptogams and invertebrates. The species composition and biodiversity of the terrestrial biome depend on the biogeographic region. The Antarctic is divided into the richer maritime Antarctic and the much poorer continental Antarctic. Prokaryotes, algae (biodiversity only now being examined) and lichens (totaling ca. 380 known taxa) are the most diverse groups in the Antarctic. There is a substantial degree of endemism among the Antarctic lichens and invertebrates, which could indicate that they are remnants of a pre-glacial flora and fauna. Alongside lichens, community-forming taxa include multiple bryophytes: 27 species of liverworts (*Marchantiophyta*) and 111 species of mosses (*Bryophyta*). The reasons for the extreme poverty of Antarctic vascular plants flora (only two native species) remain unclear. Antarctic terrestrial communities are classified according to the types of vegetation. The environmental role of the Antarctic terrestrial biome lies in the accumulation of organic matter and creation of conditions for terrestrial life in one of the most extreme environments on the planet. Its terrestrial communities are susceptible to climate change and anthropogenic pressure and require constant monitoring and protection in particular by Antarctic Specially Protected Area (ASPA) creation.

Introduction

Antarctic is extremely remote and experiences the coldest temperatures on the planet. Its biome exist in the most extreme environment on Earth, characterized by very low temperatures and lack of accessible water. In this article, we describe the distinctive features of the Antarctic terrestrial biome, which in this work will include terrestrial ecosystems as vegetated areas, as well as lakes and streams. Bacteria, algae, cryptogams and invertebrates dominate here, therefore these ecosystems are rather simple. Because of the harsh environments, Antarctic ecosystems have very low productivity. Their biodiversity is also limited by the remoteness of the region. The diversity of community types is also low due to the narrow range of environmental conditions variations. These traits contrast the terrestrial biome with the high biodiversity of the surrounding Antarctic marine biome. The Antarctic terrestrial biome is among the most susceptible to climate change. Meanwhile, Antarctica is the only one of the Earth's continents not to have a long-term history of human habitation. In view of this, its terrestrial biome requires a delicate approach and protection.

Origin

Since the first appearance of angiosperms on Antarctica in the Cretaceous, more than 100 million years ago (Ma), the Antarctic terrestrial biome has undergone a significant dramatic change (Rees-Owen et al., 2018). The initial stages of vegetation development in Antarctica are unclear due to the absence of a fossil record (Cantrill and Poole, 2012). During the Ordovician glaciation (443–458 Ma), current Antarctica was likely free of ice. During the following Permo-Carboniferous glaciation, exact time of which is debated (ca. 300 Ma), an ice sheet covered most of Antarctica (Smith, 1997). The end of the Permo-Carboniferous glaciation was accompanied by the restoration of mild humid climate and, as a consequence, all of Gondwana was covered by the seed fern *Glossopteris* forests (McLoughlin, 2011). Until 55 Ma, the history of life on Antarctica was very similar to that on other southern continents,

especially Australia. Their respective fossil records are very close, with abundant terrestrial plants and animals. There are abundant plant fossils from this period in many parts of Antarctica. In the late Triassic greenhouse world, the warm climatic conditions promoted a spread of forest vegetation far into the polar regions of southern subcontinental Gondwana (Bomfleur et al., 2014).

In the late Cretaceous a podocarp-southern beech temperate forest spread here (Fig. 1). A low diversity Antarctic tundra flora was dominated by angiosperms in the Neogene (Rees-Owen et al., 2018). Antarctica, including its offshore archipelagos, was covered by continental ice sheets from the Oligocene (ca. 60 Ma) until the Pleistocene (1 Ma). There is paleobotanical evidence that forest existed in Antarctica during the Oligocene and probably until the Miocene (12–23 Ma), relatively complex alpine communities must have persisted around the moister coastal fringes of the continent (Ochyra et al., 2008). The Last Glacial Maximum (LGM) was perhaps the most challenging for biotic survival and most of the biota went extinct. The modern flora and fauna were likely formed in two ways. The endemism of the Antarctic lichens, bryophytes and invertebrates suggests that they survived Pleistocene glaciations in refugia. Studies demonstrate the presence of refugia in continental Antarctica, at least in the Pleistocene (0.01–2.6 Ma), and possibly in the Miocene. In the maritime Antarctic, all low-altitude coastal regions are believed to have been covered by much-expanded glaciers and ice sheets during the LGM, and only reexposed as the ice retreated during the last 10,000 years. However, recent biogeographical studies indicate that this view may be overly simplistic and inaccurate at smaller scales (Peat et al., 2006). Alongside survival in refugia, it is believed that other organisms such as most bryophytes are post-Pleistocene migrants from South America or other regions. Prolonged winds are considered to have been the most important factor of transfer. Occasionally, birds could have served the same purpose. Antarctic soils contain large numbers of bryophyte diaspores that do not germinate (Ochyra et al., 2008). It remains unclear whether vascular plant refugia existed in Antarctica during glacial periods, or whether or vascular plants recolonized the continent from elsewhere, and in the latter case—when it occurred (Parnikoza et al. 2007).

Habitat and Biogeographic Zonation

Only about 2% of Antarctica is free of ice and snow. The Antarctic terrestrial biome occupies only part of this territory and consists of terrestrial ecosystems that are classified according to vegetation type, as well as biotopes of streams and lakes. Local habitat and biodiversity depend on the region of the continent or offshore islands. In terms of biogeographic zonation, Antarctic basically is divided into continental and maritime (Riffenburgh, 2007) (Fig. 2).

The continental Antarctic zone includes both the continent and its offshore islands south of Alexander Island, excluding the western side of the Antarctic Peninsula north of 70 degrees. Continental Antarctica can be divided into Ice Plateau, Slope and Coastal provinces. The Ice Plateau province has extreme continental climate with temperatures averaging less than -15°C in the summer and less than -50°C in the winter. This region receives little precipitation, no rain, and 1–3 months of continuous daylight in summer. The region is practically devoid of vegetation, even lichens, algae's and cyanobacteria. The Slope province has extremely cold and arid climate, with temperatures averaging less than -5°C in the summer and less than -30°C in the winter. Precipitation

here is less than 100 mm water equivalent, all falling as snow, no rain. There are 1–3 months of continuous daylight in summer. The Coastal province has a cold, arid climate, with monthly temperatures averaging above 0°C for 0–2 months in the summer. Winter monthly means temperatures average from -5 to -25°C with some maritime influence that narrows the temperature range. Precipitation is ca. 100–150 mm water equivalent and rain is very rare. The snow-free period at sea level is ca. 10–15 weeks. The Coastal province is the richest biotically in continental Antarctic, with relatively diverse biota in some regions, such as Joinville Island, Dundee Island, Vega Island, James Ross Island, Seal Nunataks, Cabinet Inlet, parts of the eastern and north-eastern coast of Alexander Island and Charcot Island. Parts of the coastal region of Eights Coast (Thurston Island) have probably the most diverse biota in continental Antarctic (Øvstedal and Lewis Smith, 2001; Ochyra et al., 2008).

The maritime Antarctic divided to northern part, that includes Bouvetøya, South Sandwich, South Orkney and South Shetland Islands as well as western coast of the Antarctic Peninsula to ca. 68° (66 degrees in other source) and southern part, that includes west coast of Antarctic Peninsula from ca. 68° (66 degrees in other source) to 70°S and offshore islands as well as the northeast coast to ca. 64° . The northern part of the region is characterized by a cold moist maritime climate, with mean monthly temperatures averaging above 0°C for 3–4 months in the summer, but rarely less than -10 to -12°C in the winter. The precipitation averages 350–500 mm per year, which mostly falls as rain in the summer. The snow-free period lasts ca. 15–20 weeks. The southern part has a cold dry maritime climate, with mean monthly temperatures averaging above 0°C for 1–3 months in the summer but rarely below less than -15°C in the winter. The precipitation averages less than 350 mm per year with occasional rains. The snow-free period at sea level lasts 12–18 weeks (Øvstedal and Lewis Smith, 2001; Ochyra et al., 2008).

Main Components

The uniqueness of the Antarctic terrestrial biota is that it primarily consists of microorganisms, fungi, algae, lichens, bryophytes, and invertebrates. The biology of Antarctica, more than any other continents, is dominated by microorganisms. Studies reveal a greater diversity of microbes here than had been estimated previously (Tytgat et al., 2014). Species symbiotic with plants occur among the bacteria (Cid et al., 2016). A significant role in ecosystems is also played by cyanobacteria, particularly in continental Antarctica (Pandey et al., 2004).

A substantial portion of the terrestrial and freshwater biodiversity consists of algae. Their biodiversity is only well studied for some regions, in particular for the Argentine Islands, where 78 species and intraspecific taxa of algae are known (Polishuk et al., 2009). Snow algae that use mineral elements from snow and ice are the only inhabitants of continental regions (Davey, et al., 2019). Entire microcommunities of endolithic algae are scattered in continental Antarctica (Broady, 1981).

The Antarctic terrestrial biome also includes fungi, including some specific groups, such as the fungi of cryptoendolithic communities and rock-inhabiting fungi. In the maritime Antarctic, in particular the Argentine Islands region, mushrooms of the genus *Omphalina* occur, as well as parasitic fungi, such as *Nectria antarctica* (Speg.) Rossman (Smith and Corner, 1973; Longton, 1979). Mycorrhizal fungi occur in Antarctica as well (Upson et al., 2008) (Figs. 3 and 4).

Most of the unglaciated regions of Antarctica are dominated by lichens, totaling ca. 380 known taxa. Lichens are dominate the Antarctic biome in a broad range of conditions. Only the wettest patches of cyanobacteria communities lack lichens. The epicenter of lichen biodiversity in Antarctica is the Antarctic Peninsula, harboring 264 taxa. The continental Antarctic, on the other hand, has at least 88 taxa. The small and isolated volcanic South Sandwich Islands have 46, South Orkney Islands has 221, and the South Shetland Islands has 211 taxa. The biogeography of the species is difficult to describe, as the species' distribution is poorly understood. The most species-rich genera include *Buellia* (32 species), *Caloplaca* (29), *Cladonia* (27), *Lecanora* (25) and *Verrucaria* (16). Among the Antarctic lichens, the share of cosmopolitan and bipolar species decreases southwards (Øvstedal and Lewis Smith, 2001).

Bryophytes are another group that characterizes the Antarctic biome, particularly its green part created by vegetation. The bryophytes include the liverworts and mosses. Antarctic flora of liverworts counts 27 species. There are no liverwort species endemic to Antarctica. Biogeographically this group includes 9 sub-Antarctic and 11 south temperate species, together comprising 75% of the Antarctic liverwort flora. 6 bipolar and 1 pan-continental phytogeographical elements are also present (Bednarek-Ochyra et al., 2000).

Antarctic mosses have a total of 111 species and two varieties, which is more than on some sub-Antarctic Islands, regardless of the more favorable climate on islands. The South Shetland Islands are the richest in moss species diversity and in the development of moss communities, harboring 87 species, 12 of which have not been collected from other parts to Antarctica. Some species are only known in Antarctic from the volcanic Deception Island. The moss flora of the eastern shore of the Antarctic Peninsula is rather distinctive. In continental Antarctica 24 species and 2 varieties of mosses occur. 4 species are found only in Antarctic continent. The biogeographic distribution is as follows: Antarctic endemics—11 species, sub-Antarctic species—18, south temperate—26, bipolar—50, cosmopolitan—5, tropical—1. Therefore, bipolar taxa dominate. Only five species of bryophytes collected beyond 80°S, all in the trans-Antarctic mountains, southern Victoria Land. Some species grow above the 1000 m elevation (Ochyra et al., 2008).

Vascular plants that define the face of biomes on other continents are only represented with two species in Antarctica, *Deschampsia antarctica* É. Desv. and *Colobanthus quitensis* (Kunth) Bartl. For comparison, the sub-Antarctic flora includes near 70 native species

Fig. 3 Mushroom *Omphalina* sp., Oasis Rasmussen, Graham Land, 2019. Photo by Ivan Parnikoza.

Fig. 4 Parasitic fungus *Nectria antarctica* on moss *Sanionia georgicouncinata* (Müll. Hal.) Ochyra & Hedenäs, Western Corner Island, the Argentine Islands, 2016. Photo by Ivan Parnikoza.

of vascular plants, Falklands/Malvinas—about 170 species. In the Northern Hemisphere, Svalbard had 173 species of vascular plants. Overall, the Arctic flora incorporates 900 native species. The reason for the extreme paucity of vascular plants flora in Antarctica remains unclear (Ochyra et al., 2008). In fact, alien vascular plant species outnumber the flora of Antarctica. These include *Poa annua* L., *P. pratensis* L. and *Nassauvia magellanica* J. F. Gmel., probably transferred to the continent by humans. Diasporas of other species have been reported from soils in places of high human activity (Fuentes-Lillo et al., 2017).

Invertebrates dominate the fauna of the terrestrial biome, both terrestrial and freshwater types. According to a generalizing study by Russell et al. (2014), the soils of the Antarctic Peninsula harbor 11 species of collembolan, 23 species of actinedid mites, 5 species of oribatid mites, 4 species of gamasin mites, and 39 species of nematodes (Fig. 5). The Antarctic midge (*Belgica antarctica*) is a native endemic species of Chironomidae associated with vegetation (Convey and Block, 1996) (Fig. 6). Invertebrate diversity is the result of local abundance of organic matter in the soil and the development of vegetation. Overall, ca. 30 bdelloid rotifers, ca. 70

Fig. 5 Collembolan *Cryptopygus antarcticus*, Fanfary Island, the Argentine Islands, 2016. Photo by Ivan Parnikoza.

Fig. 6 Antarctic midge *Belgica antarctica*, Grotto Island, the Argentine Islands, 2016. Photo by Ivan Parnikoza.

monogonont rotifers, ca. 70 nematodes and 62 tardigrade species are known from the entire Antarctic region (Velasco-Castrillón et al., 2014; Vecchi et al., 2016). These small numbers of identified species lead us to suspect that most of the microinvertebrates in this region are still unknown. Close to 90% of the known continental Antarctic species and almost 50% of the maritime Antarctic mesofauna are endemic (Russell et al., 2014).

Communities

Terrestrial communities of Antarctica are classified on the basis of their plant communities. Plant communities, in turn, significantly change along the north-south gradient. In the north of the region, in particular on the Southern Shetland Islands, they form continuous areas which may be described as Antarctic tundra. Here, vegetation covers wet depressions which are free of snow as early as November and through late March. In Antarctica, the ecological optimum for Antarctic hairgrass is likely located in the vicinities of Point Thomas Oasis (King George Island), where the most developed communities occur (Komárková et al., 1985). Some 400 km south from King George Island on the Argentine Islands, vegetation already exists only on elevated above the snow level patches, thus vegetation period in some seasons goes on from January to half of March. In the meantime, local habitat variations, such as microclimate and local impact by animals greatly influence vegetation. As a result of these factors, communities of different degrees of resilience may be found within single regions.

Vegetation classification for the Antarctic terrestrial communities was developed on the basis of the composition of bryophytes and lichens species (Smith and Corner, 1973; Øvstedal and Lewis Smith, 2001; Ochyra et al., 2008). The *Short moss turf and cushion subformation* is prominent. According to a different approach, this community that includes rock fruticose lichens defined as *Fruticose lichen and moss cushion subformation* (Smith and Corner, 1973). In the maritime Antarctic, it is the variant with *Usnea antarctica* Du Rietz—*Umbilicaria antarctica* Frey & I. M. Lamb. as well as *Andreaea* mosses that forms compact cushions (Fig. 7).

The *Tall moss turf subformation* is represented by assemblages of mosses with turf growth-form, some communities of which accumulate peat up to more than 1.5 m deep with permafrost about 20–30 cm below the surface, usually colonized by crustose and fruticose lichens (Ochyra et al., 2008). These communities of *Polytrichum strictum* Brid. and *Chorisodontium aciphyllum* (Hook. f. & Wilson) Broth. form moss banks that occupy large areas (which allows mapping them) (Fig. 8). The oldest moss banks are known from Elephant Island of the Southern Shetland Islands Archipelago and are believed to be ca. 5500 years old (Björck, 1991). A variant of this community, the *Campylopus association*, in Antarctic occurs exclusively on thermal patches of South Sandwich Island (Longton, 1979).

Communities formed predominately by pleurocarpous mosses of shallow turf-like carpet and prostrate mat growth-forms and similar forms of foliose and thallose liverworts are wide spread on moist soils named the *Bryophyte carpet and mat subformation* (Figs. 9 and 10). The more sporadically represented community of high hummock mosses *Bryum pseudotriquetrum* (Hedw.) P. Gaertn., B. Mey. & Scherb. and *Brachythecium austrosalebrosum* (Müll. Hal.) Kindb. is designated as the *Tall moss cushion (hummock) subformation* (Smith and Corner, 1973; Ochyra et al., 2008).

The crustose lichen community—*Crustose lichen subformation* is also wide spread in Antarctic (Fig. 11).

Among the communities dominated by algae, two types are defined: the *Alga subformation* (a community of terrestrial algae) and the *Snow alga subformation* (Figs. 12 and 13).

Fig. 7 Fruticose lichen and moss cushion subformation, *Usnea aurantiacoatra* (Jacq.) Bory association on the Fildes Peninsula, King George Island, 2019. Photo by Ivan Parnikoza.

Fig. 8 Tall moss turf subformation—*Polytrichum strictum* and *Chorisodontium aciphyllum* moss bank, Berthelot Island, Graham Land, 2019. Photo by Ivan Parnikoza.

Vascular plant communities are classified as the *Antarctic herb tundra formation*, in particular the *Grass and cushion chamaephyte subformation* (Smith and Corner, 1973) (Figs. 14–16).

In Antarctica, the ecological processes of vegetation succession are practically absent; although a gradual development of some community from colonization by the most enduring species up until others settle the prepared substrate does take place (Longton, 1979). Probably only radical habitat changes can trigger whole community exchange.

Fig. 9 Bryophyte carpet and mat subformation, a drier variant with *Sanionia georgicouncinata*. Skua Island, the Argentine Islands, 2016. Photo by Ivan Parnikoza.

Fig. 10 A wetter variant of the Bryophyte carpet and mat subformation with *Warnstorfia fontinaliopsis* (Müll. Hal.) Ochyra, Southern part of Uruguay Island, the Argentine Islands, 2016. Photo by Ivan Parnikoza.

Freshwater streams, subglacial and subaerial lakes (wherever they are brackish) form a separate component of the terrestrial biome in Antarctica. Some lakes in high latitudes have a permanent ice cover. Most of the biomass of Antarctic non-marine ecosystems accumulates in lakes. The main phototrophs in Antarctic inland waters are cyanobacteria (*Phormidium*, *Oscillatoria*, *Lyngbya*, etc.), flagellates such as *Cryptomonas* and *Chroomonas* (*Cryptophyceae*), *Ochromonas* (*Chrysophyceae*), *Clamidomonas* (*Chlorophyceae*), *Pyramimonas* (*Prasinophyceae*) as well as *Chlorococcaleans* such as *Ankistrodesmus* and *Schroederia*. In particular, cyanobacteria are the most abundant component of the freshwater ecosystems in Antarctica (Bargagli, 2005) (Fig. 16).

Fig. 11 Crustose lichen subformation at Brown Bluff, the Tabarin Peninsula, 2016. Photo by Ivan Parnikoza.

Fig. 12 Alga subformation, Brown Bluff, the Tabarin Peninsula, 2016. Photo by Ivan Parnikoza.

They occur as part of the plankton or form mats covering bottom sediments. Some mosses, such as *Bryum pseudotriquetrum*, may grow as benthic phototrophs in lakes of maritime and continental Antarctic (Bargagli, 2005; Ochyra et al., 2008).

In maritime Antarctica, lakes are enriched with animal organic matter (e.g., penguin feces) and become zones of intensive growth of aquatic mosses and algae. They can overgrow and convert to peatlands.

Phototrophs support a wide range of heterotrophic bacteria, fungi, protozoans and microinvertebrates (rotifers, nematodes and tardigrades) (Bargagli, 2005). Freshwater crustaceans occur in both maritime and continental Antarctic lakes (Bayly et al., 2003; Polishuk, 2009) (Figs. 17 and 18). Lakes also harbor a species of chironomid midge *Parochlus steinenii*. Outside Tierra del Fuego (South America), it inhabits fresh waters and probably brackish waters from South Georgia to the South Shetland Islands (Hahn and Reinhardt, 2006). The trophic structure and inhabitants of many freshwater bodies in Antarctica differ.

The Ecological Role

The main ecological role of the Antarctic terrestrial biome could be defined as the accumulation of organic matter in the extreme terrestrial habitats of Antarctic. The terrestrial biome receives organic deposits from seabirds and mammals which contributes to the development of terrestrial vegetation and soil formation. Numerous decomposers transform organic matter into accessible soil elements. The type and characteristics of Antarctic soils are strictly dependent on the available ecological condition and the local

Fig. 15 A community with participants of *Deschampsia antarctica*, Irizar Island, the Argentine Islands, 2016. Photo by Ivan Parnikoza.

Fig. 16 A community with participants of *Deschampsia antarctica*, Lagotellerie Island, the Marguerite Bay, 2019. Photo by Barbora Chattová.

degree of development of the terrestrial biome (see [Bockheim, 2015](#)). The communities formed by *Deschampsia antarctica* are particularly conducive to soil formation. Additionally the Antarctic terrestrial biome plays a significant role in the life of sea birds. In particular, kelp gulls (*Larus dominicanus*), skuas (*Catharacta*) and some other birds use vegetation for nest building ([Parnikoza et al., 2018a](#)), thus Wilson's storm petrel (*Oceanites oceanicus*) creates burrows in eroded moss banks ([Smith and Corner, 1973](#)).

Modern Impacts

For the last 50 years, the Antarctic terrestrial biome along the west seashore of the Antarctic Peninsula has experienced the effects of climate change (Turner et al., 2005). Evidence for changes in the terrestrial ecosystem comes from microarthropods communities study (Convey, 2003), from range extensions of plants (Fowbert and Smith 1994; Parnikoza et al., 2009) and from the successful establishment of alien species (Frenot et al., 2005).

Among the natural factors beyond climate change, the influence of bird colonies is notable, the largest impact being by penguin colonies. In maritime Antarctica, number and size of Gentoo penguins (*Pygoscelis papua*) colonies have increased, which is likely a result of climate change (Peña et al., 2014) (Fig. 19). Flying sea birds and pinnipeds also impact the local composition of the terrestrial biome. Flying sea birds, by using plants for nest building, also promote the spread of the terrestrial biome into new

territories. Kelp gulls create some specific biotopes as well, the so-called Gulls rocks—habitats enriched in limpet shells that are inhabited, in particular, by Antarctic hairgrass ([Parnikoza et al., 2018a](#)) (**Fig. 20**).

The Antarctic terrestrial biome has also experienced human impact during the last 100 years, chiefly due to the activity of local research stations and tourism. The former leads to transformation of the natural terrain and vegetation for station construction and

Fig. 21 Large scale transformation of a terrestrial biotopes of Fildes Peninsula, King George Island, 2019. Photo by Ivan Parnikoza.

maintenance (Fig. 21). Station operation lead to contamination of the biome with trace elements and other pollutants (Bargagli, 2005, Parnikoza et al., 2017). Meanwhile, construction also leads to the formation of habitats artificially shielded from winds, which makes them favorable for vegetation. Dispersal of aboriginal plants into human-changed environments has been reported from Point Thomas Oasis, King George Island, as well as near the Ukrainian Academic Vernadsky and US Palmer stations. At the Academic Vernadsky station, colonization of buildings and constructions of the British period (built in the 1950–70s) by crustose and foliose lichens has also been reported (Parnikoza et al., 2018b) (Fig. 22).

The second factor, tourism, has been increasing dramatically in the 21st century. According to the last IAATO reports (2019, <https://iaato.org/documents>), the total number of Antarctic visitors in 2017–18 was estimated at 51,707, an increase of 17% compared to the previous season, where the majority (41,996) of visitors traveled by sea to Antarctica on vessels offering excursions ashore. This number includes both tourists arriving to Antarctica onboard of a cruise ship accompanied by trained guides, as well as people who travel to the continent on small yachts, catamarans, etc. Independent tourists are able to get to almost anywhere because of very lax controls. These unguided intrusions pose a potentially serious threat (Fig. 23), increased tourism, among other impacts, also increases the threat of biological invasions (Fuentes-Lillo et al., 2017).

Fig. 23 Communities of fruticose and foliose lichens are incredibly susceptible to the carelessness by tourists, Eight Island, the Argentine Islands, 2019. Photo by Ivan Parnikoza.

Conservation Measures

In view of the above-mentioned, the terrestrial biome needs to be studied in detail by revision all of its most valuable components and patches, that need to be protected (Fig. 24). Initially it should be protected as part of station management plans in case of station vicinity or in frame of visiting rules in case of touristic sites. The next step might be the creation of a representative network of natural reserve areas with a protected status (strict protection, Ia IUCN)—the Antarctic special protection areas (ASPA) (Fig. 25). Existed ASPA network is not sufficient and need to be expanded. It is also necessary to expand monitoring of climate changes and human impact on terrestrial ecosystems with the involvement of a broader circle of the Antarctic Treaty countries.

Abstract

The Southern Ocean biological system is dominated by physical processes such as strong winds, ice retreat and formation, and seasonal disruption and generation of vertical stratification in the water column, although these physical features are not uniform over the entire region. Antarctic plankton respond quickly to these physical variations in stratification and nutrient inputs, resulting in a heterogeneous distribution of phytoplankton and zooplankton. Phytoplankton of the Antarctic are dominated by diatoms, but nanophytoplankton, haptophytes, and dinoflagellates are locally important. A major feature of Antarctic phytoplankton is that they are large relative to those in warmer waters, and this allows for the establishment of a shorter food web and a more direct transfer of organic matter to higher trophic levels. Antarctic krill are important macrozooplankton, but their abundance is extremely variable in waters around the continent. Copepods are also important grazers of phytoplankton and transfer energy to krill and other higher trophic levels. Microzooplankton have a relatively reduced role in the Southern Ocean, especially when compared to more tropical, oligotrophic systems. Because the physical features of the Southern Ocean are expected to change substantially in the coming century, plankton will also change, although the impacts of predicted climate change on the quantity and composition of the plankton of the Southern Ocean remain unclear. Understanding the present state of Antarctic waters is essential to forecasting the changes that will occur in the near future and to predict the impacts on Antarctic food webs and biogeochemical cycles.

Introduction

Waters surrounding the Antarctic continent are among the most physically controlled of all marine systems. Not only are the temperatures extremely low (from -2°C to 4°C), but the surface is covered by ice for a large portion of the year. The retreat and advance of ice generates substantial changes within the water column with regard to its stratification, nutrient content, and availability of light, and these in turn drive large changes in marine plankton. Furthermore, the entire Southern Ocean is dominated by the world's largest (by volume) current—the Antarctic circumpolar current (ACC). This current not only restricts exchanges with more temperate waters but facilitates exchanges of biota throughout the entire region (Hunt et al., 2016). It occurs in deep waters (ca. 3000 m), is driven by large-scale wind patterns, and its characteristics (temperature, salinity, frontal structure) have been known for decades (Sverdrup et al., 1942). It drives a circumpolar divergence which results in exceptionally high macronutrient (nitrate, phosphate) levels at the surface year round. While the definition of the Southern Ocean varies among oceanographers, this review will consider Antarctic waters to be those influenced by ice. That effectively puts the boundary at the core of the ACC (ca. 60°S), which is generally the maximum extent of ice.

Despite the importance of the ACC and other extensive currents, waters of the Antarctic are far from homogeneous. A number of marginal seas exist that have restricted exchanges with the ACC, and these areas have substantially different plankton from the waters of the ACC. These marginal seas are also shallower and encompass large portions of the continental shelf; being close to the continent, they are influenced by continental processes such as glacial inputs, winds, and exchanges with the benthos. The major

marginal seas include the Ross, Weddell, Amundsen and Bellingshausen Seas; other marginal seas exist, but they are less isolated and influenced more by exchanges with the ACC.

The global heat budget is the primary feature structuring the Southern Ocean. That is, solar energy is greatly reduced during the austral winter, and the net heat flux is negative, driving ice formation. In summer, the heat flux is positive, and forces ice melting and retreat. The annual cycle of the Southern Ocean is dominated by this process (Fig. 1). During ice formation in winter, seawater begins to freeze, forming small crystals called frazil ice, which rise to the surface. Frazil ice accumulates and is compressed into larger ice forms (pancake ice), which in turn is solidified into broad sheets of ice from 1 to 2 m thick. This ice breaks frequently under the pressure of winds and currents, creating gaps in the ice (leads), but these areas freeze quickly and generate more ice. Thus, even during winter the ice and ocean surface is a dynamic and constantly changing feature that provides a unique and variable environment for plankton. In summer, ice begins to melt. The melting seawater can generate a surface layer with reduced salinity in close proximity to the ice edge, and hence the vertical density stratification of the upper water column is increased. The strength of the stratification is a function of the rate of meltwater input and the strength and direction of regional winds, which act to mix the surface waters and disrupt the stratification.

One significant role of ice that is often overlooked is the presence of biota within the sea ice. The sea ice biota consist of autotrophs, heterotrophs and mixotrophs, and can originate from seawater during freeze-up, and be released into the surface layer during melting. This interaction introduces an unusual feature to Southern Ocean plankton, and the characteristics of this biota are treated in Thomas and Dieckmann (2002).

Plankton of the Southern Ocean

As in the rest of the ocean, there are different energetic strategies employed by Southern Ocean plankton. The first is autotrophy, or the generation of reduced carbon compounds from carbon dioxide using radiant energy produced by photosynthesis. The second is

Fig. 1 Mean distribution and percentage ice cover of sea ice in the Southern Ocean. Figure courtesy of C. Parkinson's and Nick DiGirolamo, NASA Goddard Space Flight Center.

heterotrophy, or the oxidation of organic compounds to provide energy to synthesize needed compounds within the organism. The organic compounds can be obtained by a number of “feeding” mechanisms, including the ingestion of particles, the absorption of dissolved organic matter, or a combination of both. Some organisms combine photosynthetic processes with direct use of organics (mixotrophy), but in large part plankton can be divided between auto- and heterotrophs. Microbial organisms (the so-called bacteria) have a broad diversity and ability to use organic matter, and will not be discussed here.

Phytoplankton

General features and composition

Phytoplankton in Antarctic waters have numerous characteristics that make them different from those in tropical and temperate waters. Most oceanic waters consist of cyanobacteria, diatoms, haptophytes, prasinophytes, dinoflagellates, and chlorophytes. However, in the Southern Ocean cyanobacteria are largely absent and inactive, and dinoflagellates play a relatively minor role. Coccolithophorids (a type of haptophyte) are also relatively unimportant. The reduced abundance of these forms, which can be dominant in other waters, increases the importance of the other groups. For decades, diatoms have been considered the dominant planktonic form (Fig. 2A–C), although more detailed examinations in a variety of regions demonstrate the importance of other forms as well. Haptophytes, and specifically the genus *Phaeocystis*, occur in numerous regions (Fig. 2D), and cryptomonads can also be important in some regions. The types of habitats vary not only spatially, but temporally as well. Despite the similarities in some features, such as ice cover and low temperatures, it has been recognized in recent decades that the Southern Ocean is far from homogenous. Because phytoplankton respond relatively quickly to changing environmental conditions (such as altered irradiance fields and nutrient concentrations), it is challenging to characterize the importance of various groups of phytoplankton throughout the Southern Ocean, since phytoplankton composition varies with spatial and temporal patterns in the environment.

One feature that is more easily described is the total standing stock of phytoplankton. The major pigment of autotrophs is chlorophyll, which can be quantified by the analysis of satellite imagery. While this is possible only during cloud-free periods, over longer periods of time (e.g., days, weeks to months) a composite record of phytoplankton chlorophyll can be generated (Fig. 3). Chlorophyll can be used as a measure of total phytoplankton abundance, which drops to extremely low levels from April through September (austral winter), but begins to increase as solar energy increases (and ice begins to recede). Rapid increases and accumulation of phytoplankton can occur, forming “blooms” of enhanced standing stocks. Once blooms are formed, they can be

Southern ocean phytoplankton in a changing climate. *Frontiers in Marine Science*. <https://doi.org/10.3389/fmars.2017.00040>.

disrupted by physical (vertical mixing with deeper waters) or biological (grazing, sinking) processes (Fig. 4). Some regions have sustained blooms (e.g., Ross Sea) with elevated biomass that persists for months, whereas others have shorter blooms that often are not observed from space due to their short existence. Blooms are generally dominated by only a few species that respond to the in situ environmental conditions by growing and accumulating faster than other forms. For example, *Phaeocystis* appears to grow in some iron-rich, low light environments (Smith et al., 2014; Alderkamp et al., 2012), while cryptomonads seem to be favored in waters influenced by glacial run-off (Moline et al., 1996). Diatoms also bloom within the marginal ice zone in numerous locations (Smith and Nelson, 1985; Moore et al., 1999; Vernet et al., 2008). Given the ephemeral nature of blooms and the restricted access to waters of the Southern Ocean, our knowledge of bloom composition throughout the waters surrounding Antarctica is incomplete.

An additional significant characteristic feature of phytoplankton in the Southern Ocean is their size. Many dominant phytoplankton, especially diatoms, are large (that is, greater than 50 μm in the longest dimension), and the mean size of phytoplankton in Antarctic waters is much greater than in warmer seas. This has an important ecological impact, in that larger phytoplankton can be

Fig. 4 Illustration of biological disruptors (i.e., zooplankton grazing or sinking) or processes that reduce surface phytoplankton standing stocks. Adapted from Burd, A. B. and Jackson, G. A. (2009). Particle aggregation. *Annual Review of Marine Science* 1, 65–90. <https://doi.org/10.1146/annurev.marine.010908.163904>.

grazed by larger herbivores, which in turn can be eaten by larger carnivores. This results in a more compressed food web and perhaps a more efficient transfer of carbon and energy to higher trophic levels. This is at least one factor that contributes to the large biomass of higher trophic levels (whales, seals, penguins, pelagic birds) found in the Southern Ocean (Ryther, 1969).

General distribution

The overall standing stocks of phytoplankton are well known from satellite data (Fig. 3), but the composition of those stocks is far less known. Selected regions and marginal seas have characteristic compositions that are relatively predictable (e.g., Ross Sea, where haptophytes bloom in spring and are replaced by diatoms after iron limitation occurs; Smith et al., 2014), but data for the entire Southern Ocean are lacking. Nanoflagellates can be commonly found in deeper waters and appear to represent a relatively stable assemblage, even upon manipulation of micronutrients (Schulz et al., 2018).

Controls on growth and accumulation

Phytoplankton in the Southern Ocean are considered to be limited by available resources, and more specifically, by the resource that is in the smallest supply relative to requirements. The highly seasonal nature of the environment creates a situation where one environmental resource limits phytoplankton growth for part of the year, and another for the rest of the year. The major factor controlling phytoplankton growth over much of the year is light. Light availability varies with latitude, date (solar angle), ice distribution, clouds, mixing within the water column, and ocean wave height. For much of the Southern Ocean within the Antarctic Circle, light limits phytoplankton for large periods simply because the sun falls below the horizon for much or all of the day. Even when the solar angle increases, ice (and especially the associated snow cover) absorbs and reflects much of the incoming radiation (generally more than 97% of incident radiation). Hence, one measure of light limitation is simply ice distribution.

Vertical mixing in the water column also can contribute to light limitation. This is more common in deeper, less stratified waters of the ACC, but is also important anywhere that physical processes induce deep mixing in the water column (Fischer et al., 2014). If

Fig. 5 Conceptual diagram of the “Sverdrup Hypothesis” explaining the regulation of the onset of a phytoplankton bloom by vertical mixing and irradiance. From Fischer, A.D., Moberg, E.A., Alexander, H., Brownlee, E.F., Hunter-Cevera, K.R., Pitz, K.J., Rosengard, S.Z. and Sosik, H.M. 2014. Sixty years of Sverdrup: A retrospective of progress in the study of phytoplankton blooms. *Oceanography* **27**, 222–235.

the water column is mixed to a critical depth, net photosynthesis (integrated over depth and time) cannot be positive, and no net growth can occur (Fig. 5). Only when mixing is less than this critical depth can net growth proceed. As mixed layers in the Southern Ocean can exceed 200 m (Constable et al., 2014), light limitation via mixing is a common feature controlling phytoplankton growth.

During spring and summer, when ice is melting and receding (creating stratification within the water column), mixing and light penetration into the water are no longer limiting factors. Phytoplankton then grow at their maximum rates as determined by temperature (Eppley, 1972), until another factor limits their growth—such as nutrients. Nutrients, such as N, P, Si, Fe, Ca, and a host of metals, are required for cellular synthesis and growth. Due to substantial upwelling associated with the ACC and large-scale currents, macronutrients (nitrate, phosphate), rarely drop to levels that limit phytoplankton growth. However, micronutrients, and especially iron, fall to extremely low concentrations and can limit phytoplankton growth. Bio-available iron levels are low throughout much of the ocean, and it was not until oceanographers developed trace-metal clean sampling techniques that the role of iron in regulating phytoplankton growth was elucidated. There are two sources of iron: from the atmosphere as eolian inputs, and from upwelling or mixing of deeper water. Atmospheric inputs are low throughout the Southern Ocean, as the continent is largely covered by ice and exchanges occur with air masses farther north are limited. Iron fluxes via upwelling set an upper limit to surface concentrations, but these are quite small as well, because iron is removed rapidly by biological and chemical processes (uptake, scavenging by particles). After phytoplankton growth in increased light conditions occurs, iron concentrations drop to vanishingly low levels (less than 0.1 nM; macronutrient concentrations are at least three orders of magnitude higher). Such low concentrations have been shown repeatedly to limit phytoplankton growth. While the locations where iron has been shown to be limiting are small (due to the difficulty of sampling using trace metal clean techniques), and only a few locations have physical mechanisms to provide adequate iron continuously (e.g., from glacial melt), iron is a significant factor in regulating phytoplankton growth throughout the Southern Ocean.

Phytoplankton standing stocks are regulated not only by growth and accumulation, but by losses. Losses can result from grazing by zooplankton, sinking, or lysis (the rupturing of cell membranes, either by attack from viruses or by autolysis, the destruction of cell walls by the cell's own enzymes). Grazing—the ingestion of phytoplankton by heterotrophic organisms—by micro- or meso-zooplankton can be an important process in any ocean system. In waters of the Southern Ocean, grazing is highly dependent on the stage of the phytoplankton bloom and predation on the grazers by organisms in higher trophic levels. For example, Atkinson et al. (1999) suggested that copepods (often the major grazer on phytoplankton) had their biomass and grazing impact limited by krill predation. Other studies have suggested that these grazing impacts tend to be restricted in time (e.g., Smith et al., 2011). In less productive waters, grazing can consume a significant fraction of phytoplankton productivity (Calbet, 2001; Saba et al., 2014). In contrast to tropical waters, microzooplankton grazing is generally minimal (Caron et al., 2000; Garzio et al., 2013; Mosby and Smith, 2015). Passive sinking of phytoplankton is generally slow, but more rapid sinking can occur when blooms become nutrient limited (Jones and Smith, 2017). Viral lysis of plankton cells in the Antarctic has not been studied, and autolysis is unknown.

Zooplankton

General features and composition

Like phytoplankton, zooplankton in the Southern Ocean are diverse, and have a number of characteristics that make Antarctic zooplankton different from those in temperate and tropical waters. One feature is the occurrence and importance of different types of krill (euphausiids) that are often considered to be keystone species of the Antarctic (Fig. 6A). It has been estimated that the biomass of krill is approximately 379 million tons, equal to that of all fishes in the ocean (as well as being equal to that of humans; Atkinson et al., 2009). Distribution of krill is far from spatially uniform, with the largest concentrations being found near the Antarctic Peninsula and the islands downstream from this area (Atkinson et al., 2004). The life cycle of krill is complex, with eggs sinking to depth to hatch, and the larvae migrating to the surface layer to feed within the marginal ice zone. Krill are omnivorous; they ingest a variety of particles, including diatoms, protists, and ice algae. Larval krill are often associated with ice, and total

Fig. 6 *Euphausia superba* (A), *E. crystallarophius* (B), *Salpa cylindrica* (C), *Euaugaptilus ractus* (D), dinoflagellate (E), and ciliate (F). Images courtesy of Russ Hopcroft (A, C, and D), Volker Siegel (B), and the Australian Antarctic Division (E and F). All scales are approximate.

krill biomass appears strongly correlated with ice concentrations (Loeb et al., 1997). Given the large size of adults, they can migrate vertically to great depths, and have been observed feeding on benthic phytodetritus during winter (Clarke and Tyler, 2008).

Two major types of krill occur in the Southern Ocean. The best known species is Antarctic krill (*Euphausia superba*), which is ca. 8 cm in length as an adult, and individuals can live up to 7 years (Fig. 6A). Krill are harvested commercially in certain locations of the Antarctic and form the major prey for many baleen whales, crabeater seals, large fishes, pelagic birds, and penguins. The second species is crystal krill (*E. crystallarophius*), which is smaller (adult length ca. 5 cm) and commonly found on continental shelves (Fig. 6B). It is the food of many higher trophic levels as well, but much less is known about its distributions and ecological role.

During years of low ice concentrations and distributions, krill appear to be ecologically replaced by salps (Loeb et al., 1997). Salps are urochordates that filter substantial volumes of water and can multiply rapidly, even in the cold waters of the Southern Ocean (Fig. 6C). They are capable of utilizing smaller sizes of particles than krill, and as phytoplankton tend to be smaller during years of reduced ice, salps can effectively utilize the available food during these periods. Salps and krill have a greatly different ecological role; krill are an excellent protein source for higher trophic levels, whereas salps have a large amount of water and reduced amounts of organic matter relative to their size, making them a less useful food source. Hence, the presence or absence of krill and salps has considerable ecological impact and has been shown to structure food webs of the Southern Ocean.

Another group of zooplankton which are important in Antarctic waters (and the entire ocean) are copepods (Fig. 6D). Copepods occur throughout the ocean and are a major consumer of phytoplankton, as well as the major conduit for organic matter to higher trophic levels. In the Southern Ocean they occur frequently, although their importance is often overshadowed by the presence of krill. They have been shown to be major grazing organisms in many regions of the Antarctic, and often are responsible for the majority of the metabolism by zooplankton in the surface layer (Ashjian et al., 2004). As in temperate and tropic waters, copepods are an important grazer of phytoplankton and protists, and contribute significantly to energy transfer within food webs. They also are food for krill and small fishes.

The smallest size of grazers is occupied by a variety of protists (Fig. 6E and F). These are largely single-celled organisms that can feed on smaller phytoplankton as well as larger forms. Given their small size (from 40 to 200 µm), then can grow as rapidly as phytoplankton, and thus potentially are an important means to reduce phytoplankton biomass. Examples of protists include heterotrophic dinoflagellates, ciliates, tintinnids, radiolarians, and foraminifera. While they provide some food to larger organisms such as copepods and krill, their major role is to recycle nutrients for use by phytoplankton and thus contribute to the “microbial loop” (Sherr and Sherr, 1994). In the Antarctic the role of the microbial loop is reduced relative to warmer waters, but still is important to the functioning of energy and nutrient fluxes of pelagic systems.

General distribution

Standing stocks of zooplankton can only be assessed using discrete net sampling, and as a result are far less known than that of phytoplankton. Most studies are restricted to selected regions (e.g., Atkinson et al. 1999; Steinberg et al., 2008; Smith et al., 2017). However, some estimates of distributions of some forms have been constructed. (Figs. 7 and 8). Antarctic krill have their greatest abundance downstream of the Antarctic Peninsula, an area that serves as a “seed bed” where sub-adults grow and are advected in the ACC downstream (Hofmann and Murphy, 2004). Conversely, salps have their greatest densities in areas where krill do not reach high abundances, such as the Indian and Pacific sectors off the continental shelves. Copepods have some distributional features that are similar to those of Antarctic krill (e.g., elevated abundances near the islands in the northern portions of the ACC, low abundances in the ice-covered Weddell Sea) but also shown regional maxima that are not associated with krill (e.g., high concentrations at the

Fig. 7 Distribution of unstandardized krill and salp densities in the Southern Ocean. Salp densities appears to be more variable than those of krill. Unstandardized density values are not corrected for biases relating to differing sample depths, time of day and year, and net types. From Atkinson, A., Hill, S. L., Pakhomov, E. A., Siegel, V., Anadon, R., Chiba, S., Daly, K. L., Downie, R., Fretwell, P., Gerrish, L., Hosie, G. W., Jessopp, M. J., Kawaguchi, S., Krafft, B. A., Loeb, V., Nishikawa, J., Peat, H. J., Reiss, C. S., Ross, R. M., Quetin, L. B., Schmidt, K., Steinberg, D. K., Subramaniam, R. C., Tarling, G. A. and Ward, P. (2016). *Earth System Science Data*. <https://doi.org/10.5194/essd-2016-52>.

edge of the continent near 23°E). More research is needed to extend these distributional maps to the entire Southern Ocean and to verify these patterns.

Controls on zooplankton growth and accumulation

The regulation of zooplankton biomass is far less known than that of phytoplankton, largely because it is more difficult to experimentally determine their growth, rates of ingestion, and population losses. Indeed, it is likely that different sizes and types of zooplankton experience different controls. Some groups may be food limited, given the strong seasonality of phytoplankton growth and production, whereas others can be limited by strong predation. For example, krill can accumulate to incredibly high concentrations (called superswarms; which can reach mean concentrations of 100 krill m⁻³ and stretch for multiple kilometers at 30 m; Tarling et al., 2009). At those concentrations it is likely that all food would be removed in localized patches. Similarly, food for zooplankton in the water column is extremely low in winter, and most zooplankton have evolved means to survive long periods of no food availability (e.g., storing lipids, feeding on ice and phytodetritus). In contrast, predation by penguins and whales has been suggested to be important factor in controlling krill vertical distribution (Ainley et al., 2015) and potentially biomass. Food webs in the Southern Ocean are complex, but in general have fewer trophic transformations due to the large sizes of phytoplankton and zooplankton (Fig. 9). Zooplankton standing stocks likely represent a balance between food limitation and losses due to predation by upper trophic levels.

Future Plankton

The future of Antarctic plankton is uncertain. Climate change is drastically altering environmental conditions, and associated organism climate envelopes, globally. While scientific models can predict the degree and severity of some ecological changes, the oceanic lag effect means current atmospheric greenhouse gas concentrations will have impacts for hundreds to a thousand years to come (Keeling et al., 2010). Given their latitude, polar regions and the organisms that exist there are particularly susceptible to the

Total Southern Ocean Copepod Distribution ($\#/m^3$)

J., Ressler, P. H., Subbey, S., Hofmann, E. E. and Loeng, H. (2014). Krill, climate, and contrasting future scenarios for Arctic and Antarctic fisheries. *ICES Journal of Marine Science* **71**, 1934–1955. <https://doi.org/10.1093/icesjms/fsu002>.

physical and chemical changes induced by climate change. The importance of sea ice to light and nutrient availability and the subsequent importance of light and nutrients to plankton growth was illustrated earlier; the mass, extent, and seasonal onset of changes in sea ice is changing as a result of climate change.

Phytoplankton

Because they form the base of food webs, the impacts of climate change on phytoplankton abundance, distribution, and type will determine larger changes to Antarctic ecosystems. Changes in phytoplankton dynamics will be dependent on all factors that impact their growth in any climate (i.e., nutrient availability, light availability, temperature, etc.). In the Antarctic Peninsula region, there is evidence of a transition from a diatom-dominated to cryptophyte-dominated community, likely resulting from changes in ice cover, mixing depths, and glacial meltwater input (Montes-Hugo et al., 2009; Flores et al., 2012). Like all aspects of climate change, ecological responses vary; microflagellate populations may increase as a result of increased temperatures (Flores et al., 2012), but in the Ross Sea diatoms are associated with water temperatures above 0° (Liu and Smith, 2012). Future changes in the Ross Sea have also been modeled. These results suggest that the overall importance of haptophytes will increase because future open ice periods will increase with earlier ice retreat (generating longer times for growth in a low irradiance environment; Kaufman et al., 2018). Similar modeling efforts have not been applied to the entire Southern Ocean, however.

Zooplankton

The impacts of climate change on zooplankton are non-uniform but, in general, are likely to be negative. Because of their dependence on phytoplankton for food and on adequate ice concentrations for spawning, krill populations have been curtailed with decreased ice extent and the reduction of phytoplankton blooms (Atkinson et al., 2004; Meredith and King, 2005). This decrease in krill abundance has been significant in the southwest Atlantic sector, where standing stocks, which usually account for nearly 50% of total Southern Ocean krill, have been decreasing since 1970 (Atkinson et al., 2004). Contrastingly, salps tolerate warmer water conditions and have expanded their range due to climate shifts (Atkinson et al., 2004). Because krill are a more important link in the Antarctic food web than salps, higher trophic levels in the future will likely experience population declines due to reduced krill biomass and range (Atkinson et al., 2004).

Smith et al. (2014) modeled the impacts of future changes in ice concentrations and distributions in the Ross Sea, the effects on phytoplankton, and the impacts on the food web. While they concluded that primary productivity will increase slightly in the coming century, they also suggested that the greatest impacts will be on crystal krill, as those populations are generally associated with ice and ice will decrease substantially in the next 100 years. They also predicted an increased importance of copepods and small fish (such as Antarctic silverfish, *Pleuragramma antarcticum*) that feed on copepods and serve as food for penguins, seals and other top predators. While the food web will respond to multiple changes in the future, it was concluded that the Ross Sea food web may be strongly disturbed and damaged relative to its present (and largely pristine) state.

Constable et al. (2014) reviewed the expected future changes in biota in the entire Southern Ocean. They emphasized that many habitat parameters will change regionally, although some will impact the entire Antarctic (e.g., warming, reduced salinity, strengthening of winds). They also suggested that lower trophic levels would be impacted more than higher trophic levels, but that all changes would involve numerous interactions among the habitats, physical forcing, food web ecology, and biological diversity (Fig. 10). They also made predictions on specific biological groups with respect to eight physical parameters that are expected to change. The impacts on diatoms were generally positive in waters less than 3°C and those on flagellates were negative; impacts

on copepods were uniformly positive, while those on Antarctic krill were positive in the Antarctic and negative in the sub-Antarctic. Clearly the impacts of climate change and other future changes in Southern Ocean oceanography are uncertain, and a great deal more remains to be learned about how this unique system will respond in the future.

Summary

The Southern Ocean is changing as a result of natural and anthropogenic changes. Such changes have occurred in the past, but the region is now changing faster than ever before. Given the dependence of Southern Ocean plankton on the physical environment, Antarctic plankton are expected to change dramatically as well. Despite our understanding of this change, it is challenging to document, given the difficulty of sampling at appropriate spatial and temporal scales in such a harsh environment. However, substantial progress has been made in recent years, and further advances will come with the development of new technologies to sample the remote areas of the ocean. Understanding the changes and their ecological impacts is difficult, but essential to protect and conserve this pristine environment.

Abstract

Sixteen species of cetaceans and pinnipeds frequent the Antarctic biome to various extents, from its northern limit in the Southern Ocean at the Antarctic Polar Front down to the Antarctic Continent that is fringed by numerous Antarctic islands and the seasonally contracting and expanding pack ice and fast ice. Each species is considered within Antarctic biome context, emphasizing their distribution, abundance, biomass, life history, seasonality and foraging ecology. In the face of likely direct and indirect anthropogenic impacts on Antarctic marine mammals, threats to, and the conservation status of these animals are also considered.

Introduction

This article considers only those marine mammal species found regularly south of the Antarctic Polar Front (APF), the oceanic region that marks the northern limit of the Antarctic Zone. For the 16 species dealt with here, the taxonomy, origin of species names, physical appearance and identification appear exhaustively in various publications such as [Watson \(1981\)](#), [Laws \(1993\)](#), [Reeves](#)

et al. (2002), Perrin et al. (2009), Hund (2014), Bester et al. (2017), and Würsig et al. (2018). I therefore concentrate on the distribution, abundance, body size and foraging ecology (diving characteristics and diet) of the selected species, i.e., those characteristics that make sense in a biome context and are likely to respond to the shifting of the state of the world's oceans that is magnified in polar regions. Such shifts may include increased acidity, warmer seas, higher sea levels, reduced sea ice, and regionally variable shifts in productivity and marine biodiversity (Moore, 2018). I also consider the threats to these Antarctic marine mammals in the face of perceived human impacts. These include climate change (Nicol et al., 2008; Evans et al., 2010; Massom and Stammerjohn, 2010; Turner et al., 2014; Moore, 2018), sealing/whaling, ship strikes, underwater noise, tourism, marine litter, chemical pollution, disease, and entanglement in fishing gear (Bester, 2014a; Risch et al., 2019).

Details of cetaceans and pinnipeds were gleaned primarily from Watson (1981), Laws (1993), Stewardson (1997), Rice (1998), Reeves et al. (2002), Berta et al. (2006), Best (2007), Bester and Hofmeyr (2007a); Fontaine (2007), Simmonds and Isaac (2007), Siniff et al. (2008), Perrin et al. (2009), Kovacs et al. (2012), Southwell et al. (2012), Parsons (2013), Ropert-Coudert et al. (2013), McIntyre et al., 2014; Hund (2014), Bester et al. (2017), Würsig et al. (2018), and Risch et al. (2019).

Cetacea

Based on their ecological requirements, Antarctic cetaceans can be divided into three groups: those associated with fast ice, those associated with pack ice, and those that live in the open ocean (Boyd, 2009). The Antarctic minke whale (*Balaenoptera bonaerensis*), southern bottlenose whale (*Hyperoodon planifrons*), and killer whale (*Orcinus orca*) regularly associate with the Antarctic sea ice zone throughout the year. Sperm whales (*Physeter macrocephalus*), blue whales (*Balaenoptera musculus*), and Arnoux's beaked whales (*Berardius arnuxii*) are often found at or within the ice edge during summer. Humpback whales (*Megaptera novaeangliae*) and fin whales (*Balaenoptera physalus*), both cosmopolitan cetaceans, regularly occur south of the APF and their vocalizations were detected by hydrophone in the Antarctic coastal area off the Ekström Ice Shelf in both winter and summer (vide Bester et al., 2017). The hourglass dolphin (*Lagenorhynchus cruciger*) and southern right whale (*Eubalaena australis*) also penetrate the APF. Although listed as true Antarctic species (Lowther, 2018), I disregard sei whales (*B. borealis*), long-finned pilot whales (*Globicephala melas*) and strap-toothed whales (*Mesoplodon layardii*), as they are rarely found south of the APF in the Antarctic.

Antarctic Minke Whale

The Antarctic minke whale *B. bonaerensis* (Fig. 1A) has a circumpolar distribution and is abundant from 60°S to the ice edge during summer. They also occur in the loose pack ice and polynyas, and in more consolidated ice. Some overwinter in the Antarctic, but most retreat to breeding grounds in the mid-latitudes off Australia, South Africa and Brazil. The most recent estimate of overall abundance of Antarctic minke whales is around 500,000 individuals, down from an estimated 720,000 in earlier assessments (Risch et al., 2019). Perhaps these estimates represent a real decline in minke whale numbers, although this is unclear.

This whale grows to 8.9–9.0 m and 8.5–8.6 m at maturity in females and males respectively, and they weigh an estimated 9000–10,000 kg. Estimated longevity is >40 years and the age of sexual maturity is 5–9 years in both sexes. It is thought that peak calving takes place in July and August in warmer waters at low latitudes after a pregnancy of ~10 months. The nursing period appears to last 5–6 months, with a peak in conceptions between August and November. Conception probably takes place in winter in warmer waters, and a calving interval of 14 months (equivalent to a calving rate of about four calves every 5 years) suggests that females eventually get out of phase with the breeding season, and then must pass into a resting stage once lactation has ended.

Minkes feed predominantly on euphausiids (krill), with no substantial fish component to their diet, both on their summer feeding grounds and winter migrations. At the ice edge and offshore of the ice-edge zone, krill (*Euphausia superba*) dominates their diet. They feed close to the surface. Their diving behavior is unknown, but the intervals between visible blows suggest that dives are usually rather short (most less than 2 min) and shallow (perhaps <60 m). Within the Antarctic biome they may range as far south as 65°S, but generally are more common on the feeding grounds north of 60°S during the austral summer.

Threats and Conservation Status

Minkes are fully protected in their range since a moratorium on commercial whaling began in 1986/87. Japan continues to take Antarctic minke whales annually, purportedly for purposes of scientific research. Their nonaggregating nature and remote foraging habitat shelter them from other direct interactions with human activities while in Antarctica. Perhaps the most important threat is the loss of foraging habitat accompanying ocean climate warming and constriction of seasonal pack ice. Whales that use sea ice and ice-edge habitats are at risk as they prey on species linked with the pack ice ecosystem. Antarctic minke whales are listed as "Near Threatened" under the IUCN Red List. They are included on Appendix I of CITES, as well as Appendix II of the Convention on Migratory Species (CMS).

Arnoux's Beaked Whale

Arnoux's beaked whales *B. arnuxii* (Fig. 1B) have a circumpolar distribution, ranging from the Antarctic continent and ice edge to temperate waters. Frequently found in summer in the Antarctic, and in the pack ice in August, individuals sometimes become trapped by ice and are forced to overwinter in the Antarctic. Their simultaneous presence off the coasts of southern continents and in the Antarctic in summer suggests different populations, but their wintering and breeding grounds, and their population size are unknown.

The largest known Arnoux's beaked whale is 10.06 m long. Body mass of adults, maximum life expectancy, the ages of sexual maturity and the reproductive cycle are unknown. These whales are accomplished divers, with dive durations within leads in the Antarctic pack ice averaging 35–65 min, and a maximum of at least 70 min. They are presumably cephalopod feeders, based on unidentified beaks found in the stomach of only one individual. They may also take deep-sea fish.

Fig. 1 (continued).

Threats and Conservation Status

The greatest threat to this species is the loss of foraging habitat accompanying ocean climate warming and constriction of seasonal pack ice, especially for those that use ice-edge and pack ice habitats for foraging. Arnoux's beaked whale is listed as "Data Deficient" by the IUCN, and included in Appendix I of CITES, but not listed by CMS.

Blue Whale

Antarctic blue whales *B. musculus* (Fig. 1C) have a circumpolar distribution, and are abundant south of 60°S, especially close to the edge and within the pack ice in summer. Most of these whales may not move more than 90 degrees of longitude while in high latitudes. Much of the population migrates to low latitudes in winter, although some overwinter in the Antarctic. No specific winter breeding ground is known for blue whales. After their virtual extinction by whaling, blue whale populations are increasing in the higher latitudes of the Antarctic, with perhaps a still-small population of about 1700 present in 1996.

Blue whales are the largest animals ever to have lived on Earth. Females grow to a length of 25.9 m and males grow to 24.1 m. Body weights of adults generally range from 50,000 kg to 150,000 kg, although one female specimen taken in 1947 weighed 190,000 kg. The maximum life expectancy of blue whales ranges from 65 to 70 years to greater than 80–90 years. Their age of sexual maturity is probably about 8–10 years in both sexes. The reproductive cycle is perhaps 2 or possibly 3 years, including a resting period. Calving takes place between late March and early July at low latitudes, after a pregnancy of approximately 12 months. The nursing period appears to last 7 months, followed by a resting stage, resulting in females being pregnant sometimes at intervals of more than 2 years.

Krill (*E. superba*) dominates the blue whale diet at the ice edge and in high latitudes, with copepods and amphipods also taken. Short shallow dives are most common, lasting generally 8–15 min, although 20 min dives occur frequently. Shallow dives (10–20 consecutive dives) are often followed by a deep dive of 10–30 min.

Threats and Conservation Status

This species has been fully protected from commercial whaling since 1986/87. The loss of foraging habitat accompanying ocean climate warming and constriction of seasonal pack ice may be a threat, especially for those that use ice-edge habitats. The blue whale is listed as "Endangered" by the IUCN, and included in Appendix I of both CITES and CMS.

Fin Whale

The fin whale *B. physalus* (Fig. 1D) occurs worldwide in all oceans. They migrate from summer feeding grounds in high latitudes, where they avoid the ice edges, to winter breeding grounds in lower latitudes, however, the actual locality of their breeding grounds remain unknown. South of 37°S an estimated 38,200 individuals frequent temperate and cold waters, with perhaps 2100–5500 living in the Antarctic south of 60°S.

Fin whales grow to 21 m in males and 22 m in females; sexual maturity is attained at ages of about 6–7 years in males and 7–8 years in females. Adult fin whales weigh 60,000–80,000 kg. Their life span is most likely around 100 years. Gestation is 11 months, and the calving interval is usually 2 years. The nursing period lasts 6–7 months, followed by a 6-month resting period. The nursing period rarely extends to 12–13 months.

Fin whales feed almost exclusively on krill in the Antarctic region, while during their winter migration they also take copepods, amphipods and occasionally fish (unidentified). They normally lunge-feed and their dives are limited to 100–200 m, lasting 3–10 min. Their deeper dives coincide with the upward vertical migration of krill.

Threats and Conservation Status

Fin whales have been fully protected from commercial whaling since 1986/87, although a small number is taken for scientific purposes. Collisions with vessels, incidental catches in fishing gear and anthropogenic noise are of little consequence in the remote Antarctic zone, and insignificant at the population level. This species is listed as “Vulnerable” by the IUCN, and included in Appendix I of CITES and on Appendices I and II of CMS.

Hourglass Dolphin

Only found in the southern ocean, the hourglass dolphin *L. cruciger* (Fig. 1E) occurs in areas on and south of the APF in the South Atlantic and South Pacific, and all the way to the edge of the pack ice in summer. They may migrate south in summer to higher latitudes. They are relatively common in cold southern waters, and an estimated 144,300 individuals occur south of the APF in summer.

Adult hourglass dolphin males grow to 1.78 m and adult females to 1.83 m. Body weights of adults are unknown but may reach 100 kg or more. Maximum life expectancy, the ages of sexual maturity and the reproductive cycle are insufficiently known. They seem to prey primarily on midwater species at night, including a wide range of cephalopods and both myctophid and hake fish.

Threats and Conservation Status

The remote and harsh environment associated with this species has thus far prevented large-scale human impact. Changes in foraging habitat adjacent to the constricting seasonal pack ice accompanying ocean climate warming may change this. This species is listed as “Least Concern” by the IUCN and included in Appendix II of CITES, but they are not listed by CMS.

Humpback Whale

The humpback whale *M. novaeangliae* (Fig. 1F) a cosmopolitan species of baleen whale, moves between summer feeding grounds in high latitudes within the APF and winter breeding grounds in lower latitudes. It does not enter the pack ice zone, but forages up to the ice edge during summer. Some humpbacks remain in the Antarctic during winter. Heavily exploited in the past, there are possibly about 80,000 in the Southern Hemisphere as of 2015.

Mature humpbacks typically grow to 11–17 m and weight 20,000–35,000 kg, although in the past some grew to 19 m and weighed as much as 40,000 kg. The heaviest specimen on record was a male that weighed in at 59,400 kg and was 14.2 m long. This whale stranded in July 1995 (Best, 2007). The estimated longevity of humpback whales is 45–100 years with the age of sexual maturity about 4–5 years in both sexes. Females have their first calf at around 11–12 years. Gestation is 11–12 months, with the females producing calves usually every 2 years. The nursing period lasts 10.5–11 months.

Humpbacks have a diet that varies with season and foraging area. They feed on krill *sensu lato*, amphipods, stomatopods (mantis shrimp) and pelagic schooling fish. They forage near the surface, extending down to 15 m, and are known to dive to 150 m. Deep dives last < 10 min in summer and about 15–20 min in winter. These dives can extend to 45 min. Hunting for food is a communal effort on the higher latitude feeding grounds in summer.

Threats and Conservation Status

Humpbacks are resilient to depletions, and it appears that stocks are recently recovering. Entanglement in fishing gear or collisions with ships take a toll, but these hazards appear insignificant at the population level. Being a very vocal species during migration and

breeding, anthropogenic noise may impact the species, although less so in the Antarctic biome. Humpbacks are now listed as “Least Concern” by the IUCN, and included on Appendix I of both CITES and CMS.

Killer Whale

The killer whale *O. orca* (Fig. 1G) is a cosmopolitan dolphin species with the highest densities in high latitudes and largest numbers occurring in Antarctica. An overall pattern of migration is suggested, with most killer whales found in warm waters in winter and in high latitudes in summer. Killer whales recorded south of 60°S in mid-winter within the pack ice might be restricted to an “ecotype(s)” that might forego migration. Killer whales present a range of behavioral, social and morphological characteristics that are interpreted as evidence to categorize individuals or groups. Although morphologically distinct forms (Type A, B, C, and D) seem to occur in the Southern Ocean, ecotypic status classification for Southern Ocean killer whale morphotypes lacks sufficient evidence-based ecological and taxonomic data (de Bruyn et al., 2012). The Antarctic summer population was estimated at about 80,400 in the period 1976–1988.

Killer whales grow up to 9.0 m, though the females rarely exceed 7.9 m. Adults weigh from 3079 to 7903 kg. The maximum lifespan of males is 50–60 years, and females live about 80–90 years. The age of sexual maturity is about 12–16 years in females and 10.5–17.5 years in males, with physical maturity attained at a mean age of 21 years. Calving may take place year-round, with peaks in autumn and spring depending upon locality, after gestation periods of 15–18 months. The nursing period lasts about 18 months. Estimated average calving intervals in the Antarctic are between 3.5 and 5.2 years. Females give birth for the first time at 12–16 years.

Killer whales feed on just about anything at sea, especially marine mammals, fish, birds, and turtles. Diet specialization amongst different communities of killer whales in the Northern Hemisphere, broadly classified as fish-eating (residents) and mammal-eating (transients), may also have developed amongst killer whales within the Antarctic. They hunt singly or cooperate to hunt large prey such as cetaceans and to maintain balls of baitfish. They also steal fish from long-lines and scavenge on discarded fishery bycatch.

They generally dive to depths below 150 m, reaching a maximum of 330+ m, but remain mostly in the top 20 m of the water column. Group diving and surfacing can become synchronized and regular with a series of short, shallow dives (e.g., 5–12 dives of 10–30 s), followed by a dive, perhaps deeper, that can last 3–5 min. Dives of up to 30 min are common, but killer whales do not have well-defined and characteristic blowing and surfacing behavior.

Threats and Conservation Status

This species frequently scavenges fish from long-line and other hook-and-line fisheries in the Southern Ocean, resulting in large losses of catch. Fishermen purportedly retaliate by shooting offending killer whales. Ocean climate warming and the resultant constriction of seasonal pack ice may have an influence on killer whales that perhaps preferentially frequent pack ice habitats. Killer whales are listed as “Data Deficient” by the IUCN, and are included in Appendix II of CITES, and CMS.

Southern Bottlenose Whale

Southern bottlenose whales (*H. planifrons*) have a circumpolar distribution, ranging from the Antarctic ice edge to temperate waters, generally south of about 30°S. Frequently sighted in summer from October to March in the Antarctic, they can occur at the ice edge, their highest densities being within 111 km of the ice edge. Sightings suggest a migratory pattern with a northwards movement from higher latitudes in late summer, and a movement back south again in spring, but their wintering grounds are unknown. They are abundant, with an estimated 600,000 beaked whales south of the APF, mostly southern bottlenose whales.

Adult males reach a length of 7.0 m and adult females 7.45 m. Body weights of adults are unknown but may reach at least 3400 kg. Maximum life expectancy, the ages of sexual maturity and the reproductive cycle are not known, apart from a female of 5.7 m lactating. They are cephalopod feeders and squid of both Antarctic and Subantarctic origin were isolated from only two stomachs (collected in mid-latitude South African waters), while a stomach from south of the APF at Heard Island (15 species of nine families of squid) also had remains of Patagonian tooth fish. Likely to be accomplished divers, dive durations of an hour or more are punctuated by blows every 30–40 s. Dive cycles recorded for 12 groups of beaked whales (presumably mostly bottlenose whales) in the Antarctic had mean submergences of 25.3 min, interspersed with surfacing bouts of on average 3.7 s.

Threats and Conservation Status

This species has little direct involvement with fisheries. Loss of foraging habitat accompanying ocean climate warming and constriction of seasonal pack ice might play a role. The southern bottlenose whale is listed as “Least Concern” by the IUCN and included in Appendix I of CITES, but not listed by CMS.

Southern Right Whale

The southern right whale *E. australis* (Fig. 1H) occurs throughout the middle latitudes of the Southern Ocean, between approximately 20 and 60 degrees latitude. They migrate from southern middle latitudes as winter begins and stay more-or-less near continents where they breed near coastlines. The total number of southern right whales may exceed 25,000–30,000 animals.

These whales grow to 12–18 m as adults, and weigh up to 60,000 kg, with the females being slightly larger. The largest known specimens weigh in excess of 100,000 kg. They become sexually mature at 8–10 years, and the females produce calves every 3–5 years. Their life span ranges from 50 to more than 70 years. They are skimmer and lunge-feeder specialists, taking krill, primarily *E. superba* in the Antarctic. However, in the lower latitudes they also feed on other euphausiids, amphipods, copepods and fish (unidentified). Feeding occurs at or near the surface, although sometimes much deeper. Their dives last for 10–20 min.

Threats and Conservation Status

Indications are that global climate change and warming sea-surface temperatures drive this species' population dynamics (Leaper et al., 2006). Inadvertent entrapment in fishing gear and collision with ships, although unlikely in the Antarctic, may have a negative effect. The southern right whale is protected throughout its range. This species is listed as "Least Concern" by the IUCN and included on Appendix I of both CITES and CMS.

Sperm Whale

Widely distributed in both Northern and Southern Hemispheres, the sperm whale *P. macrocephalus* (Fig. 1I) is the largest of the toothed whales. They occur from the tropics to the Antarctic ice edge. Only adult males move from tropical and temperate waters to the ice edge in summer, with females and immatures seldom found beyond 40°S. Movements and migrations are associated with food availability. Sperm whales were heavily exploited from the early 18th century to the late 20th century, and their worldwide population is estimated at 360,000, down from a prewhaling population of about 1,110,000.

Sperm whales grow to 17.3 m, although males of 20 m or more are known from historic records. Females rarely exceed 11.7 m. Adult sperm whales weigh from 10,800 kg to in excess of 32,700 kg. Their maximum life expectancy (both sexes) is at least 60–70 years, and age of sexual maturity is about 9 years, although males only reach social maturity at an age of 25–27 years. The reproductive cycle perhaps lasts 4–6 years, with calving between January and April, after a pregnancy of 15–16 months. The nursing period apparently lasts on average 2 years, the next calf being born after an interval of about 5 years. Large, mature males in their late 20s and older return to tropical breeding grounds to mate, and usually roam independently between groups of females.

Sperm whales principally eat medium-sized squid, and they also take demersal and mesopelagic fish, amongst others. Giant squid (*Architeuthis* spp.) and jumbo squid (*Dosidicus* spp.) are also taken. Males eat species that are largely restricted to higher latitudes such as the colossal squid, *Mesonychoteuthis hamiltoni*, of Antarctic waters. While foraging, sperm whales make repeated deep dives with a modal depth of 600 m. These dives last about 45 min. Recovery periods between dives at or near the surface are about 9 min. Dives can be deeper (to over 1000 m), shallower (depending on the bathymetry) and longer (over an hour). The longest recorded dive lasted at least 2 h 18 min, while the deepest was to 2035 m.

Threats and Conservation Status

The most abundant of the large whales, and fully protected from commercial whaling by the IWC moratorium on commercial whaling since 1986/87, interactions between sperm whales and longline fishing for Patagonian toothfish, may have an effect. Inadvertent entrapment in fishing gear and collision with ships, although unlikely in the Antarctic, may have a negative effect. Sperm whales are listed as "Vulnerable" by the IUCN and included in Appendix I of CITES, and on both Appendices I and II (presumably different populations) of CMS.

Pinnipedia

Four phocid species, the crabeater seal (*Lobodon carcinophaga*), leopard seal (*Hydrurga leptonyx*), Ross seal (*Ommatophoca rossii*), and Weddell seal (*Leptonychotes weddellii*), are intimately tied to the circumpolar Antarctic sea ice. Another phocid, the southern elephant seal (*Mirounga leonina*), and one otariid species, the Antarctic fur seal (*Arctocephalus gazella*), breed almost exclusively on both Antarctic and Subantarctic islands and some age/sex classes migrate seasonally to the sea ice to forage. Occasional visitors to the Antarctic biome such as the Subantarctic fur seal *A. tropicalis*, are not considered here.

Antarctic Fur Seal

The Antarctic fur seal *A. gazella* (Fig. 2A) breeds on Southern Ocean islands, mostly south of the APF (Hofmeyr et al., 2016) primarily at South Georgia. Numerous smaller populations within the Antarctic biome breed on Bouvet, Heard, McDonald, Kerguelen, South Shetland, South Sandwich, and the South Orkney islands. There are an estimated 2–3 million Antarctic fur seals (Hofmeyr et al., 2016).

Adult females may grow to ~1.45 m and weigh 50 kg. Adult males grow to 2 m and weigh 230 kg. Females may live to about 23 years and become mature sexually at ~2–5 years, pupping after a gestation period of about a year. Males may survive to 14 years and become mature sexually at ~3–4 years and socially at ~7 years when they may control harems on breeding colony beaches. The age of first pupping is 3 years, and all females pup by age 6 years, usually producing one pup at a time. The breeding season extends from late November to late December, with the peak pupping date in the range 4–8 December, and births are highly synchronized, 90% occurring within ~21 days. Males are fiercely territorial during the breeding season when they mate with females within about 7 days after these females have given birth to a pup. Subsequently, females undertake foraging trips of about 1 week long, punctuated by periods of ~3 days ashore to attend to their pups, although overnight trips also take place. Weaned at 4 months old, pups finally depart to sea after molting their black pelage. Molting of older animals is gradual and completed by the time they become pelagic. Females remain at sea continually between breeding seasons, although some return

Fig. 2 Antarctic pinnipeds. (A) Antarctic fur seals, (B) crabeater seals, (C) leopard seal, (D) Ross seal, (E) southern elephant seals, and (F) Weddell seals. (A) Photograph by C. Oosthuizen, MRI. (B) Photograph by N. Lübcker, MRI. (C) Photograph by C. Oosthuizen, MRI. (D) Photograph by M. Wege, MRI. (E) Photograph by H. Bornemann, AWI. (F) Photograph by H. Bornemann, AWI.

to their breeding localities for short periods during winter. Male Antarctic fur seals migrate southward during the postbreeding period.

Males dive deeper (~354 m) and longer (~9 min) than females (~208 m and ~4 min). These seals are nocturnal foragers, employing short, shallow dives throughout the night (~1 min to ~15 m depth, rarely >126 m). Deeper, longer dives occur towards dawn and dusk as they presumably follow vertically migrating prey. They usually take myctophid fish, cephalopods, krill, pelagic icefish, and nototheniids, but their prey varies geographically and within areas and seasons. Males may also kill and eat gentoo, king and macaroni penguins.

Threats and Conservation Status

Killer whales *O. orca* and leopard seals *H. leptonyx* prey on fur seals. Their foraging range overlaps with fishery activities, especially long-lining and trawling. Individuals frequently become entangled in lines, hooks and strapping which may result in death. Probable sensitivity to climate-change related alterations in habitat and predator responses are potential threats (e.g., [Forcada et al., 2005](#)). This seal's population size and distribution are likely influenced by changes in their food resources due to significant sea ice loss, leading to open water and the possible resultant expansion of the krill fishery in the future.

The Antarctic fur seal is listed as "Least Concern" on the IUCN Red List and is protected under legislation of the various states that have sovereignty of island sites; within the Antarctic Treaty Area it is protected under the Protocol on Environmental Protection to the Antarctic Treaty, but it is no longer designated a specially protected species. However, it is fully protected under the Convention for the Conservation of Antarctic Seals (CCAS) and the Convention on the Conservation of Antarctic Marine Living Resources (CCAMLR).

Crabeater Seal

Breeding populations of crabeater seals *L. carcinophaga* ([Fig. 2B](#)) are confined to the circumpolar pack ice of Antarctica ([Hund, 2014](#)). Most abundant in pack ice habitats and rarely frequenting open waters, they tend to stay over the continental shelf during the breeding season, but are more widespread in the pack ice during summer and autumn. An Antarctic-wide estimate of crabeater seals ranges between 7,000,000 and 15,000,000.

Crabeater seals grow to 2.65 m long, rarely 277 cm, and adults weigh around 210 kg, rarely attaining 410 kg. Females are usually larger than males. Their maximum longevity is 40 years, but a typical life span is 20–25 years. They mature sexually at approximately 4–5 years of age. Pups are born from October to early November, perhaps into December, the exact timing varying by region. Mating presumably takes place in the water in pack ice habitats from December to early January, within approximately 4 days after females wean their single pups following about 2–3 weeks of nursing, the exact timing of which may vary regionally. Pupping season probably varies with location. Crabeater seals molt through January to March.

The mean dive depth ranges of these seals is from 40 to 140 m, rarely to 713 m, and usually lasts less than 5 min. Diving patterns vary seasonally, preferentially during darkness. They haul out during daylight in summer and autumn. Overall, these seals dive deeper in winter (average 92 m, range 6–713 m) and longer (on average 5.26 min, range 0.2–23.6 min). During winter they also haul out during the night rather than the day ([Burns et al., 2004](#)). Diurnal or diel patterns in the diving behavior of the seals are likely in response to diel vertical migrations of prey. Seasonal shifts in foraging patterns, consistent with foraging on vertically migrating prey, also occur. Contrary to what their name suggests, crabeater seals feed primarily on Antarctic krill, but also eat fish and cephalopods when krill is not available.

Threats and Conservation Status

Climate-change related alterations in habitat and constriction of seasonal pack ice will likely affect them most. A major krill consumer, recent rapid environmental change has led to sea ice loss and a less predictable, declining krill biomass is likely to have detrimental effects. Sea ice loss will reduce suitable breeding and resting habitat, as well as protection from predators. It will also increase the distance these seals must travel to reach feeding grounds. These factors may combine to potentially reduce food for pack ice seals in general, and for crabeater seals in particular ([Forcada et al., 2012](#)).

Crabeater seals are listed as "Least Concern" on the IUCN Red List. They are protected under the Protocol on Environmental Protection to the Antarctic Treaty. Crabeaters are also protected under the CCAS, Annex I of which provides for commercial harvests of limited numbers, as do the CCAMLR, Article II.

Leopard Seal

The breeding populations of leopard seals *H. leptonyx* ([Fig. 2C](#)) are confined to the circumpolar pack ice of Antarctica ([Hund, 2014](#)). They occur all around the Antarctic continent and are most abundant in pack ice and fast-ice habitats especially along the Antarctic Peninsula. An Antarctic-wide estimate of leopard seals is somewhere between 220,000 and 440,000.

Leopard seals grow to about 4.5 m long and weigh up to 600 kg, with females being larger than males. Maximum longevity is possibly up to 25 years, and sexual maturity may be attained at 4–5 years of age. Pups are likely born from October to mid-November. Mating occurs from December to early January, evidently in the water, at about the same time as females wean their pups. Females likely nurse their pups for a month, or perhaps less. The exact timing may be dependent on the region of the Antarctic and the pupping season probably varies with location. Leopard seals molt through January to February.

Leopard seals are primarily short (~2 min) shallow divers, mostly to depths of 10–50 m and only occasionally ≥ 200 m. They feed on a variety of prey including fish, cephalopods, crustaceans, penguins, and other seals. The composition of their diet varies between seasons and regions.

Threats and Conservation Status

The nonaggregating nature and remote breeding habitat of leopard seals shelter them from direct interactions with commercial fishing activities. The most important threat may be the loss of breeding habitat accompanying ocean climate warming and constriction of seasonal pack ice. The effects of changes in sea ice on leopard seal foraging seem unlikely to be detrimental since they often forage at considerable distances from the continent, beyond the sea ice. Population size and distribution may be altered through changes in food web dynamics. Their nonbreeding season foraging north of pack ice zones may overlap with southern elephant seals, Antarctic fur seals and other migratory Subantarctic marine vertebrates.

Leopard seals are listed as “Least Concern” on the IUCN Red List, it is protected in its range under the Protocol on Environmental Protection to the Antarctic Treaty and under the CCAS, Annex I of which provides for commercial harvests of limited numbers, as does the CCAMLR, Article II.

Ross Seal

Ross seal *O. rossii* (Fig. 2D) breeding populations are confined to the circumpolar pack ice of Antarctica (Bester and Hofmeyr, 2007b; Hund, 2014). Areas of higher density appear to be in the Ross Sea, the King Haakon VII Sea and perhaps parts of the western Weddell Sea. An Antarctic-wide population estimate is 130,000–220,000 individuals.

Ross seals reach 2–2.5 m and weigh up to 216 kg. Their estimated longevity is 21 years with age of sexual maturity at 3–4 years for males and 2–7 years for females. Pups may be born from mid-October through November, mating probably occurring in December and early January. The nursing period seems to be 13 days in mid-November, and perhaps up to a month overall, with mating occurring at the end or shortly after the nursing period, likely from the last week of November. Exact timing depends on the region of the Antarctic and the pupping season probably varies with location. Ross seals molt from late December, but especially through late January to early February. Just after the molt in February, adults head north and stay pelagic in the area south of the APF, until October when they go south into the pack ice.

Throughout the year they make about 100 dives a day, mostly to a depth of 100–300 m, the deepest being 792 m. Most dives, outside the breeding and molting period, last for 5–15 min. They feed on mid-water Antarctic silverfish, squid, and to some extent krill (*E. superba*), when in the pack ice, and myctophid fish and several species of squid, when in the open ocean.

Threats and Conservation Status

The apparent solitary behavior and broad distribution of nonbreeding seals may reduce direct interactions with commercial fishing activities. The loss of breeding habitat accompanying ocean climate warming and constriction of seasonal pack ice may be a threat. However, the latter might not be detrimental since Ross seals often forage at considerable distances from the continent, beyond the sea ice. Population size and distribution may be altered through changes in food web dynamics and their foraging habitats north of pack ice zones outside of the breeding and molting seasons may overlap with southern elephant seals and other migratory Subantarctic marine vertebrates.

Ross seals are listed as “Least Concern” on the IUCN Red List, it is protected in its range as Specially Protected Species under Annex II to the Protocol on Environmental Protection of the Antarctic Treaty, and under the CCAS.

Southern Elephant Seal

South of the APF, southern elephant seals *M. leonina* (Fig. 2E) breed almost exclusively on islands and occasionally on seasonal pack ice near Signy Island, South Orkney Islands (Laws, 1956; Le Boeuf and Laws, 1994). Large populations breed on South Georgia, Iles Kerguelen and on Heard Island with numerous smaller populations primarily on the South Shetland, South Sandwich and the South Orkney islands (Hund, 2014). Elephant seals primarily use beaches for breeding, and vegetated areas inland from breeding beaches during the month long molt haul-out. A Southern Ocean wide estimate of their numbers is around 650,000 (de Bruyn et al., 2016).

Females may grow to about 2.8 m and weigh up to 900 kg. Adult males are considerably larger, growing up to 5 m in length and weighing up to 5000 kg. They live to 23+ years; females become sexually mature at about 2–6 years, while males are able to breed at

about 4–5 years but mature socially at 6–8 years. The majority of breeding bulls are 9–12 years old. Females aged 3–23+ years give birth to single pups from late September to early November, usually within aggregations of two or more females. The largest known aggregation was 1600 females, observed on Heard Island in October 1985 (Bester, 2014b). Pups nurse for a period of 3 weeks, to late November, with the timing of events usually delayed at higher latitudes. Just before the pups wean, females mate on land with dominant beachmasters, including with assistant beachmasters in harems greater than 60 females. After the breeding season, adults depart to sea, then return for a drastic molt on land from December to March, with younger age classes commencing the molt as early as November.

Elephant seals dive deeply, feeding primarily in the mid-water regions of the water column at depths of around 200–600 m. Their dives last about 20–30 min, and go as deep as 2133 m. These very deep dives may last 2 h. They spend up to 90% of their time at sea, diving with surface intervals of ~2–3 min. They show diel diving patterns, diving to shallower depths at night, and to greater depths during the day. These diving patterns are likely a response to vertically migrating prey. Myctophid fish and cephalopods are the usual prey, although their diet may vary substantially with latitude as well as within areas and seasons.

Elephant seals move predictably: there is a postbreeding pelagic period of about 2–3 months in females (approximately late October to mid-January) and of about 6 months in males, where they may remain in reasonably well circumscribed areas during their 8 month postmolting period. Their feeding grounds are 2000–3100 km distant from shore. These numbers vary in different populations and with the bathymetry of their foraging areas, as well as whether the animals use a pelagic or benthic diving strategy (McIntyre et al., 2011, 2012). Elephant seals from a number of breeding populations in particular exploit the marginal sea ice zone and areas of increased productivity associated with the ice edge, whilst avoiding areas of persistent ice cover. They also exploit areas of high sea-ice concentrations (e.g., Tosh et al., 2009), usually seals tracked from high latitude breeding colonies, such as those located around the Antarctic Peninsula and some of the southern-most islands.

Threats and Conservation Status

Depleted populations of elephant seals have recovered under protection after commercial exploitation, but then their numbers declined from the 1950s. A subsequent stabilization followed, and their numbers are currently increasing. Their foraging ranges overlap with fisheries activities, especially long-lining for Patagonian toothfish, and individual seals frequently become entangled in lines and hooks. The distribution and abundance of the ice-tolerant southern elephant seal will be the least negatively influenced by changes in pack ice characteristics due to climate change. Population size and distribution may also be influenced by changes in their food resources due to factors other than climate.

Southern elephant seals are listed as “Least Concern” on the IUCN Red List. It is also protected under legislation of the various states that have sovereignty of island sites. Within the Antarctic Treaty Area they are protected under the Protocol on Environmental Protection to the Antarctic Treaty, the CCAS and the CCAMLR.

Weddell Seal

The breeding populations of the Weddell seal *L. weddellii* (Fig. 2F) are largely confined to the circumpolar fast ice and some pack ice habitats of Antarctica (Hund, 2014). They primarily use fast-ice and nearby pack ice habitats close to the coast. Small populations also breed on South Georgia, the South Sandwich Islands, the South Shetland Islands and the South Orkney Islands. A continent-wide estimate of Weddell seals is approximately 800,000, although it may exceed 1,000,000 individuals.

Weddell seals may grow to about 3.3 m long and weigh up to 550 kg. Females may be slightly larger than males. They live to at least 25 years and females mature sexually at about 3–6 years; males mature at about 7–8 years. Weddell seals give birth to single pups, mostly within colonies of up to 50 females, from late September to early November, depending on location. Pups nurse for periods of 7–8 weeks, to December. After the pups wean, females mate in the water with dominant males that defend underwater territories (maritories) in fast-ice habitats. Adults molt from December to March.

Weddell seals dive deeply, feeding primarily in the mid-water regions of the water column at depths of around 100–300 m, and to about 600 m for up to 82 min. They may also exhibit diurnal feeding patterns within two depth layers (0–160 m and 340–450 m) as a response to vertically migrating prey. Fish (mainly Antarctic silverfish, Antarctic toothfish, several species of nototheniids and myctophids), followed by cephalopods and crustaceans, are the usual prey. There appears to be substantial geographic variability in prey taken, as well as considerable variability within areas and seasons.

Adult Weddell seals are reluctant to leave the fast-ice where they bred until March or April. They then mostly remain within 50–100 km of their summer breeding colonies, although some seals move longer distances and spend long periods in heavy winter pack ice. Year round occupancy of maritories might give an advantage for resident males over nonterritorial males or males that move away in winter, because the resident males are already there when the females begin to arrive at the breeding sites. In East Antarctica they forage off-shore within pack ice in winter for periods of up to 30 days, but return to the stable fast-ice to haul out. There is no predictable migration in Weddell seals.

Threats and Conservation Status

Changes in the extent, persistence and type of annual sea ice through climate change may negatively affect the distribution and abundance of Weddell seals. Population size and distribution may be altered through changes in food web dynamics. Changes in sea ice may negatively affect Weddell seal foraging because they forage on species that are linked with the pack ice ecosystem.

The Weddell seal is listed as “Least Concern” on the IUCN Red List and it is protected in its range under the Protocol on Environmental Protection to the Antarctic Treaty, the CCAS, Annex I of which provides for commercial harvests of limited numbers, as does the CCAMLR, Article II.

Conclusion

Overall, Antarctic seals are currently adequately protected directly by CCAS (1978) and indirectly by protection of the ecosystem upon which they rely through CCAMLR (1982), the latter also providing indirect protection for cetaceans through ecosystem management (Lowther, 2018; this study). In addition, Annex II to the Protocol on Environmental Protection to the Antarctic Treaty (1998), Conservation of Antarctic Fauna and Flora (see Lukin, 2014), provides further protection. Overall, a major issue for Antarctic marine mammal conservation is the uncertainty surrounding their population sizes and the infrequency of censuses. It is therefore impossible to detect anything but very large changes, making any response to developing threats difficult. The influences of shifts in the world’s oceans such as increased acidity, warmer seas, higher sea levels, reduced sea ice, and regionally variable shifts in productivity and marine biodiversity (Moore, 2018) would be difficult to detect. Human impacts such as sealing/whaling, ship strikes, underwater noise, tourism, marine litter, chemical pollution, disease and entanglement in fishing gear currently have little impact in the Antarctic marine biome. Current fishing levels are not an issue, but increases in catch levels or changes in the spatial distribution of fishing effort have the potential to cause negative impacts. However, the biggest threat to Antarctic marine mammals, in particular those species dependent upon sea ice for breeding, resting and refuge from predators, is climate change and any subsequent changes in sea ice. Access to feeding grounds, whether within the pack ice and/or along its outer edge, has implications for all species, as sea-ice reduction is expected to negatively impact on their food availability.

Acknowledgments

I am indebted to Scott Elias (University of Colorado) who generously allowed use of his blue, humpback and sperm whale images. Simon Elwen from Sea Search provided me with images taken by Darren du Plessis (southern right whale) and Sarah Golaski (fin whale). Horst Bornemann (Alfred Wegener Institute, Helmholtz Centre for Polar and Marine Research) provided the images of Arnoux’s beaked whales, southern elephant seals and Weddell seals. Huang Huang (GEOMAR, University of Kiel) allowed use of his minke whale and killer whales images. Bruce Dyer (Department of Environmental Affairs, South Africa) contributed the hourglass dolphins image. Nico Lübcker (crabeater seal), Chris Oosthuizen (Antarctic fur seals and leopard seal) and Mia Wege (Ross seal) from the MRI contributed their images.

Abstract

The investigation of Antarctica, the last continent to be discovered, began in earnest with European expeditions in the early 20th century. Their aim was to reach the South Pole before the competition. Major scientific expeditions began in the 1950s, especially during the International Geophysical Year of 1957–58, when 12 nations built research stations and carried out scientific projects. Geophysical survey transects across the continent, combined with aerial photography, began the extremely labor-intensive task of mapping the continent and estimating the thickness of ice cover. Ice thickness measurements and the identification of bedrock features beneath the ice were greatly aided by aerial radar surveys and satellite remote sensing in recent decades. The radar studies revealed the presence of hundreds of subglacial lakes, and ice-core drilling down to the ice-water interface allowed the sampling of lake waters, which were found to harbor micro-organismic life. Isotopic and trace gas studies from the thousands of layers in Antarctic ice cores have provided crucial evidence of global climate change through the last 800,000 years, encompassing 10 glacial-interglacial cycles. Life in the small ice-free regions consists almost exclusively of microbes and fungi: primitive organisms that have demonstrated remarkable adaptations to life in the most extreme environments of the planet.

Introduction

The human history of Antarctica has unfolded over the past three centuries. It began with European ships entering Antarctic waters in the late 18th century, followed by some brief landings in the 19th century. The early 20th century was an age of heroic exploration, with several parties of Europeans going incredible lengths to be the first to reach the South Pole, where they could plant their country's flag. Since the 1950s, international cooperation, guided by the provisions of the 1959 Antarctic Treaty, has led to many remarkable discoveries about this frigid, desolate continent that has been called "The Last Place on Earth" (Huntford and Theroux, 1999).

History of Antarctic Exploration

Let us begin with the written history of Antarctic exploration, keeping in mind the possibility that prehistoric visits to Antarctic waters by the Maoris of New Zealand may have taken place, according to their legends. Sailing in Antarctic waters has always been dangerous. The wooden ships of the 18th and early 19th centuries were quite vulnerable to the enormous waves, hurricane-force winds, and crushing pack ice of the Southern Ocean. The first explorer to circumnavigate Antarctica was Captain James Cook. Cook set sail from England in July 1772, and by December his ship, *Discovery* entered Antarctic waters, encountering icebergs. They crossed the Antarctic circle in January 1773, and then were forced to head north again because of pack ice. In December 1773 and again in January 1774 *Discovery* sailed across the Antarctic Circle, entering the Amundsen Sea at latitude 71° 10'S. Finally, in February 1775, Cook's ship completed the circumnavigation of Antarctica.

Captain Thaddeus von Bellingshausen commanded Russia's first Antarctic voyage of exploration. On January 15, 1820, Bellingshausen's flagship, the *Vostok*, crossed the Antarctic Circle. Travel further south was blocked by the Finibul Ice Shelf. He and his crew were the first to see the Antarctic continent. The following year this expedition became the second to circumnavigate Antarctica, 44 years after James Cook.

The first people to actually set foot on Antarctica may have been sailors from the American sealer *Cecilia*, commanded by Captain John Davis. They landed at Hughes Bay (64°01'S) on February 7, 1821 and remained on land less than an hour, having found no seals. The first well-documented landing on the continent was on 24 January 1895, when the Norwegian whaling ship *Antarctic*, under the command of Captain Leonard Kristensen, landed a party at Cape Adare in the northern Ross Sea.

Another important 19th century voyage to Antarctic seas was led by Captain James Weddell of the British brig *Jane*. In February 1823 Weddell entered what is now called the Weddell Sea. Later that month his ship reached 74°15'S – the furthest south anyone had ever gone, and a record that would stand for more than 80 years.

In the 1830s, the French, British and American governments funded marine expeditions to find the South Magnetic Pole. The first of these voyages was led French captain Jules-Sebastien-Csar Dumont d'Urville in the ship *Astrolabe*. In February and March of 1838, d'Urville surveyed parts of the Antarctic Peninsula. During a second southern excursion d'Urville's ships reached within 4 miles of the continent. In January 1839, some of d'Urville's sailors landed on a small island close to the shore, and claimed the land they had seen for France. D'Urville named it Adélie Land, after his wife.

In August 1838, an American expedition set sail with 6 ships and 433 crew—the largest expedition ever sent to the Southern Ocean. This fleet was commanded by Lt. Charles Wilkes. Their first penetration of southern waters was along the coast of the Antarctic Peninsula, and yielded no new discoveries. The second excursion was more successful, and Wilkes charted several hundred miles of new coastline, starting with Cape Hudson in Adélie Land on January 16, 1840 and ending with what is now called the Shackleton Ice Shelf on February 21. There were several inaccuracies in Wilkes' charted positions, however, such that James Clark Ross later sailed over some areas where Wilkes had drawn land on his charts. As with d'Urville, ice prevented Wilkes from more southerly penetrations, but much of the area he charted is now known as Wilkes Land.

First Landing on the Continent

James Clark Ross, a British explorer, set out to find the South Pole in 1839. Ross had already found the north magnetic pole in 1831, so he was experienced in navigating polar waters. Ross' flagship was the *Erebus*. The men spent the austral winter of 1840 in Australia. On January 9, 1841, Ross's ships entered what is now called the Ross Sea. Two days later they sighted a range of mountains that Ross named the Admiralty Range. On January 12 he landed on Possession Island and claimed the land for England. Further southerly exploration was eventually blocked by an ice shelf, now called the Ross Ice Shelf. Having sailed so far south, Ross determined that the south magnetic pole lay inland on the continent. After Ross' voyages there was, with a few notable exceptions, a 50 year hiatus in Antarctic exploration. The attentions of governments had turned to the Arctic and the search for the Northwest Passage.

By the end of the 19th century, the world at large was becoming more fully aware of this unexplored continent. Accordingly, the 6th International Geographical Congress passed a resolution in 1895:

The exploration of the Antarctic Regions is the greatest piece of geographical exploration still to be undertaken. In view of the additions to knowledge in almost every branch of science which would result from such a scientific exploration, the Congress recommends that the scientific societies throughout the world should urge, in whatever way seems to them most effective, that this work should be undertaken before the close of the (19th) century.

Before the start of World War I, scientific expeditions to Antarctica had been carried out by teams from Australia, Belgium, England, France, Germany, Japan, Norway, Scotland, and Sweden. The most widely publicized Antarctic expeditions at the start of the 20th century were the groups from Britain and Norway that vied for the honor of being the first to reach the South Pole.

Roald Amundsen, a 39-year-old Norwegian explorer, spent most of his adult life venturing in the Polar Regions. He had been to Antarctica in 1897–99, when he served as first mate on the *Belgica*, the ship of the Belgian Antarctic Expedition. The *Belgica* was trapped in pack ice off an island west of the Antarctic Peninsula. The crew endured an Antarctic winter in the ice. From 1903 to 1906 Amundsen led a naval expedition that successfully traversed the Northwest Passage. In 1909, Amundsen had planned to reach the North Pole, but he was beaten to this by American explorers Frederick Cook and Robert Peary, who claimed to have reached the pole that year. Without telling his financial backers or even his crew at first, Amundsen sailed the *Fram* to Antarctica to make a try at reaching the South Pole. He sent a telegram to Scott, who was still in Australia. It read simply: "Beg leave to inform you *Fram* proceeding Antarctic. Amundsen." Amundsen's plan to reach the South Pole was simpler than Scott's. Amundsen would use only sled dogs, sledges, and men on skis to reach the pole (Fig. 1).

Captain Robert Falcon Scott was a British Royal Navy officer who led two expeditions to the Antarctic. The first of these, called the Discovery Expedition (1901–04), did not reach the South Pole, but Scott's team set a new southern record by reaching latitude 82°S. They also discovered the Antarctic Plateau, on which the South Pole is located. The relative success of this mission spurred the Royal Navy to send Scott on a second trip to Antarctica, known as the Terra Nova Expedition (1910–13).

Amundsen set up camp on the Ross Ice Shelf in the Bay of Whales, a location about 100 km closer to the Pole than Scott's base at McMurdo Sound. And unlike Scott, whose expedition was burdened by its scientific obligations, Amundsen was focused only on reaching the Pole and returning safely. "Science," he later admitted, "would have to look after itself."

After spending the early part of 1911 laying down advance caches of food and supplies for their polar journeys, Amundsen and Scott's expeditions took shelter and spent several months waiting out the dark and frigid Antarctic winter. On October 20, 1911,

Fig. 1 Amundsen and his men at the South Pole, 14 December 1911. Photo courtesy of the National Library of Australia.

weather conditions improved enough for Amundsen's five-man team to begin their dash to the Pole. Scott got underway just a few days later on November 1 (**Fig. 2**).

Amundsen and Scott had very different plans for their polar excursions. Scott brought along sled dogs, Manchurian ponies and some newly invented motorized tractors. One of the tractors sank while being off-loaded from the ship, and the others quickly broke down. The ponies struggled to walk on snow and ice, grew weak, and had to be shot. Scott decided to send the sled dogs back to base camp, so he and his team were forced man-haul their heavy supply sledges on foot (**Fig. 3**). This was a critical error,

Fig. 2 Map of West Antarctica, showing the routes to the South Pole taken by Amundsen and Scott in 1911.

Fig. 3 The Scott expedition team on their way to the South Pole. Photo courtesy of the Scott Polar Institute, Cambridge, United Kingdom.

because the men hauling the sledges burned far more calories per day than they were taking in through their rations. A later analysis of the expedition estimated that even under optimistic assumptions their rations contained little more than half the calories actually required for the man-hauling of sledges. Amundsen, meanwhile, relied solely on skis and sled dogs to cross the ice. The Norwegian team took 4 sledges and 52 dogs. Amundsen's plan was to kill most of the dogs along the way, to provide fresh meat for his men. The dog sleds, accompanied by men on skis, allowed Amundsen's party to achieve a pace of over 20 miles per day, and they accomplished this in just eight-hours of travel. Their team rested 16 h a day. After crossing the Ross Ice Shelf, the team spent 4 days reaching the top of the uncharted Axel Heiberg Glacier. Having arrived at the edge of the Polar Plateau on 21 November, they took just 23 days to cross the plateau, arriving at the South Pole on 14 December 1911. Five men and 16 dogs reached their destination. Amundsen planted the Norwegian flag and posed for pictures, but they only remained at the South Pole for a few days before beginning their return to base camp. On return to base camp, the men on Amundsen's team actually gained weight. This is in sharp contrast to Scott's party, who were slowly starving throughout their journey. Six weeks after reaching the pole, the Norwegian team returned to their base camp (25 January 1912). The five men returned with 11 surviving dogs. On January 17, 1912, Scott's team reached the Pole. Much to their dismay, they spotted the tent left by Amundsen, with a letter for Scott left inside (Fig. 4). "Great God!" Scott wrote in his diary. "This is an awful place and terrible enough for us to have labored to it without the reward of priority."

The return to base for Scott's team quickly became a disaster. The weather was turning much colder and Scott's men were surviving on meager rations. When reached food and fuel caches, they discovered that much of their fuel had evaporated, so they were forced to eat frozen food. The first of Scott's party to die, Edgar Evans, succumbed on February 17. Scott had ordered that dog teams be sent from base camp to meet the polar expedition party on their way back, but through a series of disobeyed orders, mishaps, and bad weather, the dog teams never reached Scott's party. On March 16, Lawrence Oates sacrificed himself

Fig. 4 Scott's team at the South Pole, standing by the tent erected by Amundsen, 34 days earlier. Photo courtesy of the Scott Polar Institute, Cambridge, United Kingdom.

by leaving his tent and wandering off in the snow. Finally, the last three members of the team: Scott, Edward Wilson and Henry Bowers died of starvation and exposure during a blizzard, on or about March 29. By the time the three bodies were found in November 1912, Amundsen had already returned to a hero's welcome in Norway.

The next high profile exploration of Antarctica came in 1928–30. Richard Byrd, an American naval aviator, had begun flying airplanes to remote regions in 1926. He was the first to fly over the North Pole in a trimotor monoplane. This flight brought Byrd great fame in America. He was promoted to the rank of Commander and awarded the Congressional Medal of Honor. Byrd's next mission was to fly over the South Pole and to explore previously uncharted regions of Antarctica. This expedition was the first major American exploration in Antarctica since 1840, and it launched new American interest in Antarctica. The expedition landed on the Ross Ice Shelf and established a base called "Little America." Photographic expeditions and geological surveys were launched that Antarctic summer, and then the expedition's three airplanes were buried in the snow for the upcoming winter. As the Antarctic summer was beginning on November 28, 1929, a crew of four flew south in a Ford trimotor airplane, the *Floyd Bennett*, in an attempt to reach the pole. Byrd acted as navigator, accompanied by pilot Bernt Balchen, co-pilot/radioman Harold Gurnee, and photographer Ashley McKinley. Shortly after midnight on November 29, 1929, they flew over the South Pole. They refueled at a fuel dump part way to the pole, and then returned to Little America, completing a trip of 18 h, 41 min.

Post-War Research

After the Second World War, the U.S. Navy Antarctic Developments Project, Operation Highjump, was launched in 1946–47. This project was organized by Byrd, who by this time was a Rear Admiral in the United States Navy. This was the largest ever Antarctic expedition, with more than 4700 military personnel on 13 ships, and 33 aircraft. The expedition was organized into five task forces. During 1946–47 they flew over more than 1.5-million square miles of the continent, scouting for possible locations for permanent bases of operation, and gathering electromagnetic, geological, geographic, hydrographic, and meteorological data. Another U.S. Navy expedition, Operation Windmill followed in 1947–48. This effort included the use of ship-based helicopters to obtain geodetic ground control points to help locate the exact locations of aerial photos taken the year before.

Human habitation of Antarctica is extremely difficult and costly, as everything except freshwater must be brought in from other parts of the world. The first permanent camps built in Antarctica were research bases funded by the governments of several countries. One of the overriding themes of the Antarctic story is that the development of all kinds of new technologies made possible every advancement in Antarctic research. The establishment of remote bases in Antarctica would have been impossible without the development of large, powerful cargo planes, reliable tracked vehicles for over-the-snow transportation, and ships with reinforced hulls that could successfully navigate pack ice in order to reach Antarctic shores. These transportation technologies became available in the 1940s and 1950s. The scientific exploration of Antarctica only became possible as new technologies were developed for mapping the depth and movement of the ice cover, for drilling long ice cores, and for the analyses of small ice samples for trace elements, isotopes, and other constituents of ancient ice.

The Cold War environment of the 1950s spurred both the USSR and the United States to launch various forms of arms races. Doel (2003), a political scientist, pointed out that "Cold War tensions helped make Earth's polar regions valuable new targets of research." The polar regions (especially the Arctic) were considered strategic geographic regions by both sides. Scientific research, especially the field of Geophysics, played a critical role in assessing the physical environment of the Polar Regions. This is one reason that the two super powers were keen to participate in the International Geophysical Year research in the polar regions.

IGY and the Antarctic Treaty

Antarctic research received a large boost from studies performed under the auspices of the International Geophysical Year (IGY), which took place in 1957–58. Before the IGY, the legal status of the Antarctic was unfixed and largely undefined (Collis and Dodds, 2008). IGY was proposed by the international scientific community as a comprehensive global study of geophysical phenomena and their relationships with solar activity. IGY included studies of an array of areas of scientific interest including meteorology, geophysics, glaciology, oceanography, and seismology. Antarctica was considered an area of major importance, and 12 nations participated in IGY Antarctic programs. The complicated geopolitics of competing land claims and scientific research programs in Antarctica are discussed in Collis and Dodds (2008) and by Doel (2003).

The idea for an international scientific year came in 1950, when it was proposed that scientists take advantage of increasing technological developments to study the Polar Regions. Preparations for the IGY began in Antarctica in 1955. First, coastal research bases were established in the summer of 1955–56. Inland stations were established just before the official opening of IGY on July 1, 1957. A total of 18 months of intensive research was accomplished. Fig. 5 shows the locations of 25 research bases built during IGY, and their nationalities. In addition to bases established on the Antarctic mainland, 25 bases were also established on the Antarctic Peninsula and nearby islands.

IGY proved to be a hugely successful scientific experiment, demonstrating that many nations could work cooperatively in the Antarctic. Perhaps the greatest contribution was the political moratorium by the governments and the cooperative interchange between scientists of participating nations. The spirit of cooperation that evolved during IGY prompted proposals that this unique scheme should be continued, leading to formation of the Antarctic Treaty in 1959. The Scientific Committee on Antarctic Research (SCAR) was established in February 1958 to continue the international coordination of scientific work in Antarctica. It was

Fig. 5 Map of Antarctica, showing the location of research stations built for IGY projects in 1957–58, and the nationalities represented.

acknowledged that continued international scientific cooperation in Antarctica needed to be codified and to be agreed by all concerned nations. SCAR members worked closely with diplomats from the various countries to develop a treaty.

Twelve countries signed the Antarctic Treaty in December 1959, including Argentina, Australia, Belgium, Chile, France, Japan, New Zealand, Norway, Poland, Russia (USSR), South Africa, the United Kingdom, and the United States of America. The treaty paved the way for peaceful scientific research on the continent without the political ambitions of countries claiming parts of the continent for themselves. The main points of the treaty were as follows:

1. No military use shall be made of Antarctica, though military personnel and equipment may be used for peaceful purposes.
2. There will be complete freedom of scientific investigation.
3. Antarctic Treaty Nations will exchange plans for their scientific programs, scientific data will be freely available and scientists will be exchanged between expeditions where practical.
4. All territorial claims are put aside for the duration of the Treaty. No activities under the Treaty will affect claims to sovereignty of any part of Antarctica made by any nation.
5. Nuclear explosions and nuclear waste disposal are banned from Antarctica.
6. The Treaty applies to all land and ice shelves south of 60° South, but not to the seas.
7. All Antarctic stations and all ships and aircraft supplying Antarctica shall be open to inspectors from any Treaty nation.
8. Observers and exchange scientists shall be under the jurisdiction of their own country regardless of which national station they may visit. National laws do not apply to stations or areas, but only to the citizens of those countries.
9. Treaty nations will meet to consider ways of furthering the principles and objectives of the Treaty. Attendance at these meetings shall be limited to those countries that are engaged in substantial scientific research activity in Antarctica. Unanimous approval will be necessary for any new measures to become effective (i.e., everyone has to agree).
10. All Treaty Nations will try to ensure that no one carries out any activity in Antarctica that is against the Treaty.
11. Any dispute by Treaty Nations, if not settled by agreement, shall be determined by the International Court of Justice.
12. The Treaty may be modified at any time by unanimous agreement. After 30 years any consultative Party may call for a conference to review the operation of the Treaty. The Treaty may be modified at this conference by a majority decision.
13. The Treaty must be legally ratified (agreed to) by any nation wishing to join. Any member of the United Nations may join as well as any other country invited to do so by the Treaty Nations. All notices and records are deposited with the Archives of the United States of America.

The Treaty entered into force on 23rd of June 1961, and as of 2019 there are 53 signatory nations.

The Protocol on Environmental Protection was added to the Antarctic Treaty and signed in Madrid on October 4, 1991. It entered into force in 1998. Article 2 designates Antarctica as a “natural reserve, devoted to peace and science.” Article 3 sets forth basic principles applicable to human activities in Antarctica and Article 7 prohibits all activities relating to Antarctic mineral resources, except for scientific research. Until 2048 the Protocol can only be modified by unanimous agreement of all Consultative Parties to the Antarctic Treaty. The Environment Protocol established a Committee for Environmental Protection (CEP) as an expert advisory body to provide advice and formulate recommendations to the Antarctic Treaty Consultative Meeting (ATCM) in connection with the implementation of the Environment Protocol. The CEP meets every year in conjunction with the ATCM.

Studies of Antarctic Ice Properties

As late as the early 1950s, little was known of the properties of the Antarctic continent, including the volume of ice stored there, and how this had changed through time. As discussed above, Antarctic expeditions up to this point had mainly been adventurous, rather than scientific. Also, the technology required to perform widespread surveying of the ice sheet and the land beneath had not yet been developed (Siegert et al., 2018). The invention of geophysical techniques such as seismic sounding, coupled with the development of glaciology as a scientific discipline, allowed the first serious attempts to measure ice thickness, starting with a Norwegian–British–Swedish expedition to East Antarctica in 1952. Much greater progress was made during the IGY in 1957–58. A review of IGY research in Antarctica is presented by Naylor et al. (2008). These studies showed that Antarctica was one landmass—a fact unknown prior to this time. The IGY studies also demonstrated that the West Antarctic Ice Sheet (WAIS) rests on a bed as much as 2 km below sea level, while much of the East Antarctic ice sheet covers bedrock that is largely above sea level (Fig. 6).

U.S. research in Antarctic during the IGY focused mainly on measuring ice thickness, accumulation rates, and temperatures. The research questions of the project were as follows: What is the present area and volume of the Antarctic ice and of the land beneath? What is the present status of the ice sheet in terms of mass and energy? What is the history of the Antarctic continent? What is the future of Antarctica? What are the main characteristics of the floating ice shelves? Many of these questions were barely addressed during the IGY, but would help direct the course of much of the Antarctic research agenda in subsequent decades.

Three methods were used to study the thickness of the Antarctic ice sheets. First, seismograph units were placed at Byrd, Wilkes, South Pole and Hallett stations. Seismograph data can be used to study the dispersion characteristics of shock waves from earthquakes, providing data used to determine ice thickness over bedrock. Second, seismic reflection and refraction studies were used along a series of traverses. These traverses radiated out from Little America, Byrd, and Ellsworth Stations (Fig. 7), using large tracked vehicles called Snowcats (Fig. 8). They covered almost 10,000 km across the continental interior and some ice shelves. In seismic reflection studies, a hole is drilled in the ice, an explosive charge is detonated in the hole, and the characteristics of the resulting shock waves are used to estimate the thickness of the ice cover. The actual methodology was described by John Behrendt (1998).

Fig. 6 Map of bedrock in Antarctica. Note the *deep blue* regions that are below modern sea level. Image courtesy of the Bedmap Consortium, British Antarctic Survey.

We lay out our 1200-ft seismic cables in an L shape, which we unrolled from chest reels. We would hand-drill a four-inch diameter hole from 6 to perhaps 25 ft. (2–8 m) deep, usually at the apex of the L. We fired a small explosive charge of one to five pounds of ammonium nitrate detonated with an electric blasting cap and a one-pound high-explosive primer charge. The sound waves penetrated to the ice-water contact (in the case of the floating ice shelf) and to the water-rock (or ice-rock) contact and reflected back to the surface where they were picked up by the geophones. Each of the 24 geophones was attached to one of the channels in the cables.

When completed in 1959, these traverses provided a broad coverage of the WAIS and the land beneath. Third, gravimeter observations were taken in order to supplement the seismic data, allowing some interpolations of ice depths between seismic depth points, and in “no-reflection” areas. The elevation of various parts of the ice sheet was also measured during the traverses, using altimeters on land and in over-flights by airplanes. Extensive aerial photography was used to map the topography of the ice sheet, and to map exposed ranges and nunataks (exposed mountain peaks). More detailed and extensive surveys of ice thickness have been undertaken since the end of the IGY project, using increasingly more sophisticated technologies. Technology drove ice-sheet research forward again in the late 1980s and early 1990s, with the invention of satellite remote sensing, especially the European Remote Sensing satellite (ERS-1), which yielded highly accurate measurements of the ice surface elevation, and Radarsat, which produced detailed images of ice surface morphology (Siegert et al., 2018).

The Bedmap2 project, an international collaborative effort, has obtained the most recent estimates of Antarctic ice volume. Their project (Fretwell, 2013) estimated that Antarctica holds about 26.5 million cubic km of ice. It is difficult to imagine such large numbers, but if all the Antarctic ice melted, global sea level would rise by 58 m. The Bedmap2 project included 60 scientists from 35 institutions in 14 countries. The Bedmap2 ice thickness grid is made from 25 million measurements. The methods used by the Bedmap2 project to measure ice thickness included radio-echo sounding data from airborne and ground based sources, seismic surveys, swath and gridded bathymetric data, satellite elevation data, pre-gridded elevation datasets, contour data from rock outcrops, glacier profiles, grounding lines and visual interpretation of the ice sheet-ice shelf interface. The project benefited greatly from the many airborne radar surveys flown during the previous 20 years. Radar surveying is particularly useful for measuring ice thickness over bedrock. Unlike rock, ice is transparent to radar. Radio pulses are fired through the overlying ice sheet and return echoes are recorded. Using the radar reflection data, it is possible to measure the distance to bedrock. By subtracting the surface elevation of the ice sheet at that point, the depth of ice cover can be calculated. Fig. 9 is a surface elevation map Antarctica. Ice cover on the continent ranges from no ice cover in the Dry Valleys of Antarctica to a maximum ice thickness of 4776 m at a region known as the Astrolabe Subglacial Basin. The Bedmap2 project scientists estimate that the mean thickness of the Antarctic ice sheet is 2160 m. This project has also revealed a serious threat to the stability of the WAIS. Ice loss in West Antarctica is being driven by marine ice sheet instability. Changing ocean currents are bringing warmer water into contact with the floating ice shelves, causing

Fig. 7 Map of Antarctica, showing the seismic traverses undertaken during the IGY project in 1957-58.

Fig. 9 Map of the elevation of the ice covering Antarctica. Courtesy of Bedmap Consortium, British Antarctic Survey.

the melting of ice at the grounding line (i.e., the point at which the marine shelf ice meets bedrock). Grounding line recession is a real concern. If it continues unabated, there will be significant ice loss to the WAIS.

Ice Core Research

Ice cores are typically drilled by means of either a mechanical or thermal drill. Both types of drills cut a circle, around a central, vertical core. Ice drilling technology has improved more-or-less continuously since the first attempts in the 1950s. A mechanical drill is a rotating pipe (drill barrel) with cutters at the head. When the drill barrel is rotated, the cutters incise a circle around the ice to be cored until the barrel is filled with ice. In deep ice drilling, the drill barrel is driven downwards by an electromechanical motor (**Fig. 10**). The length of the drill barrel determines the maximum length of a core section that can be retrieved in a single drill run. Ice cores are typically retrieved in sections that are 1–6 m in length, and typically 50–132 mm in diameter ([National Science Foundation Ice Core Facility, 2018](#)). The collection of a long ice core thus requires many repetitive cycles of lowering the drill, cutting a core section, raising the drill back to the surface, removing the ice core section from the barrel, and readying the drill to go back down the hole to retrieve more ice. In Antarctic drilling, the retrieved sections of ice cores are typically stored in a snow cave below the surface, where extremely cold temperatures are relatively constant. At depths of about 300 m or more, the borehole may start to close up during the drilling process, because the plastic nature of ice causes it to flow under pressure. To keep the borehole open, a drilling fluid is pumped into the borehole. This fluid ensures that the pressure in the borehole is approximately the same as that of the surrounding ice, which prevents closure of the borehole. One of the great logistical difficulties to be overcome in ice sheet drilling is simply the difficulty of working at extremely low temperatures (**Fig. 11**). At -50°C and colder (not atypical temperatures for most of the interior of Antarctica), metal becomes brittle and tends to break. Fluids freeze. Motor bearings seize up when their lubricating oil solidifies. It is noteworthy that the Russian crew drilling the Vostok ice core worked through the Antarctic winter, when temperatures dropped below -70°C . The long-term storage of ice cores is done at special facilities, where the temperatures are maintained at -36°C . It was discovered that at temperatures between -20°C and -30°C , the oxygen trapped in the air bubbles in the ice eventually diffuses out of the ice.

Cores from polar ice sheets were first taken in Greenland in the 1950s. A history of the first 50 years of Antarctic ice core research is presented by [Jouzel \(2013\)](#). The first Antarctic ice core was drilled by the Russians near their Mirny station in 1957. This core recovered ice to a depth of 377 m. The first attempt at deep-hole ice drilling was done by the Russians at their Vostok station. This coring operation started in April 1970, reaching a depth of 506.9 m after 5 months of drilling. An international consortium of Russian, French and American scientists has worked at the Vostok site from the 1980s onward, and their drilling at the Vostok site culminated in the recovery of the deepest ice core thus far obtained: 3623 m. In 2012 they were able to extend the Vostok ice core drilling down to the bottom of the ice at a depth of 3769 m, where they encountered water from subglacial Lake Vostok. These extremely long ice cores represent great lengths of time. A core of 2755 m, taken in 1994, contained ice that accumulated over two

Fig. 10 Drawing of the ice coring rig used in the drilling project at Gamburtsev Subglacial Mountains, East Antarctica. Illustration courtesy of the Geological Society of London.

Fig. 11 Ice coring camp at Law Dome, 2008. Photo courtesy of Australia Antarctic Division.

glacial-interglacial cycles (Jouzel et al., 1996). A core of 3350 m in length at Vostok was taken in 1996. The base of this core has an estimated age of 420,000 years before present (yr BP) (Petit et al., 1999). The greatest time interval yet achieved in an ice core comes from the Dome C ice core. As discussed below, the ice from this core spans the last 800,000 years. Fig. 12 shows the locations of important ice coring localities in Antarctica.

Once an ice core has been drilled, it is vital to establish a chronology as precisely as possible.

On cold-based ice sheets, such as those in the Antarctic interior, no ice mass is lost by internal melting. However, because ice is plastic in nature, it deforms under its own weight, and therefore the layers become progressively thinner with depth (and age). The upper 50–150 m of an ice sheet consists of consolidated snow, known as “firn.” Air is continuously trapped in the lower 10% of the firn, at the firn–ice transition, where the interstitial spaces around the firn grains are progressively closed off until the air, trapped in minute bubbles within the ice matrix, is permanently isolated from the overlying atmosphere (Schwander, 2013). Because the firn

Fig. 12 Map showing the locations of important ice coring sites in Antarctica.

layer remains permeable to gases, the air above the firn–ice transition region is able to exchange with the atmosphere via diffusion and convection. As a consequence, the age of the air in a sample of an ice core differs from the absolute age of the ice.

Seasonal variations in temperature and atmospheric circulation are reflected by variations in trace substances and stable isotopes in ice core layers. The classic method for tracing seasonal variations in ice cores is the analysis of the ratios of the stable water isotopes $^{18}\text{O}/^{16}\text{O}$ and $^2\text{H}/^1\text{H}$. As these isotopic ratios are strongly affected by the condensation temperature of precipitation, they reflect seasonal temperature variations. In the consolidated ice (i.e., below the firn layer), the self-diffusion of the water molecules is much smaller than diffusive transport in the firn, and seasonal variations in the oxygen and hydrogen isotopes are preserved for many thousands of years. Trace substances are generally less affected by diffusion, especially particulate matter. However, there is always a lower limit of the annual accumulation rate, below which the annual variations are lost. The dating of ice older than can be counted by annual accumulation is done through a combination of techniques, including ice-flow modeling and orbital tuning. Antarctic ice cores are often drilled on ice divides or local domes because of the relatively simple pattern of ice flow. At such sites, all ice retrieved in a core originates from snow deposited in the vicinity of the drill site. The orbital tuning method is based comparisons of observations of long-term changes in the concentrations of CO_2 , methane, and other gases with the known timing of glacial-interglacial cycles based on long-term changes in Earth's orbit around the Sun, which are thought to be the main drivers of glacial cycles. Trace markers of known age, such as volcanic tephra layers, are used to correlate same-age surfaces across different cores.

The reconstruction of paleotemperatures based on ice core data is based on a number of proxies trapped in the ice. Chief among these are the deuterium-hydrogen ratios (δD), $^{18}\text{O}/^{16}\text{O}$ ratios ($\delta^{18}\text{O}$), and CO_2 and methane levels found in minute air bubbles trapped in the layers of ice. **Fig. 13** shows a reconstruction of departures from modern temperatures based on δD measurements from the Dome C ice core. The ice from this deep core spans the last 800,000 years, encompassing 10 glacial-interglacial cycles (Lüthi et al., 2008). These very long time series allow paleoclimatologists to study the duration and intensity of past climatic events.

Fig. 13 The Dome C temperature anomaly record with respect to the mean temperature of the last millennium (based on original deuterium data interpolated to a 500-year resolution). The numbers above the curve are marine isotope stage numbers, signifying glacial intervals (even numbers), and interglacial intervals (odd numbers). After Lüthi, D., LeFloch, M., Bereiter, B. et al. (2008). High-resolution carbon dioxide concentration record 650,000–800,000 years before present. *Nature* **453**, 379–382.

In addition to the stable isotope data, the network of ice cores from Antarctic sites have yielded concentration data on CO₂, methane, and aerosols that show strong linkages with global climate on many timescales (Brook and Buizert, 2018). These records demonstrate long-distance connections between Antarctic climatic events and those of distant locations. Antarctic ice research has shown that the Earth's atmospheric composition has changed dramatically over the last 800,000 years. Further coring is now being planned, but in extremely difficult locations of the continent. The goal of the new research initiatives is to find even older ice, if it exists. Older records, perhaps pushing beyond 1 million years old, will help climate scientists unravel the mechanisms underlying the shift of glacial events from 40,000-year to 100,000-year cycles that took place about a million years ago.

Subglacial Lakes

One example of multinational collaborative research in Antarctica is the exploration of subglacial lakes. These are bodies of fresh water sitting on the bed of the ice sheet. Their existence was scarcely even considered before radar mapping of the continent was carried out. The history of subglacial lake research has been summarized by Siegert (2018). The first of these lakes beneath the ice sheet was discovered from data collected on one of the first long-range survey flights in 1969. An unusually flat subglacial radio-echo surface beneath the Russian Sovetskaya Station in East Antarctica was attributed to a thick layer of water beneath the ice. Shortly thereafter, an inventory of subglacial lakes documented the presence of 17 bodies of water beneath the ice in East Antarctica. In the 1990s, satellite observations of ice-surface altimetry, such as the data generated by the European Remote Sensing satellite (ERS-1), combined with radio echo sounding data, confirmed in 1996 that Lake Vostok is over 240 km long and more than 50 km wide. Between 1997 and 1999, additional remote sensing data indicated that at least some of the subglacial lakes are not isolated, but rather are connected by streams, for instance in bedrock trenches. The flow of water between subglacial lakes demonstrated that there is an active hydrological system beneath the ice. An inventory of subglacial lakes in 1996 identified the location of 77 lakes. This number rose to 145 subglacial lakes in an inventory taken in 2005 (Fig. 14), then it rose again in 2012 and 2016, and now stands at 402 lakes (Siegert, 2018). A study by Seroussi et al. (2017) showed that a source of geothermal heat called a mantle plume was most likely responsible for the creation of lakes and streams of water beneath Marie Byrd Land in West Antarctica (Fig. 15). Mantle plumes are localized columns of hot magma rising by convection in the mantle.

Since the end of the 20th century, SCAR has facilitated this line of research, culminating in a field program to measure and sample three individual lakes in 2012/13. These were Lake Vostok, led by a Russian team; Lake Ellsworth, led by a British team; and Lake Whillans, led by an American team (Siegert, 2018).

Life Beneath the Ice Sheet

Lake Whillans was the first subglacial lake to be accessed and sampled in 2013, following the development of protocols to prevent contamination of lake water during the sampling process.

Water and sediment samples were taken, examined at the surface, and then sent to laboratories in the United States. They showed that water within Lake Whillans contained living micro-organisms, and that the lake water was mostly glacial ice melt water, with a small amounts of seawater. Glaciological study of the region showed that it had been subjected to seawater inundation during

Fig. 14 Map showing the location of 145 Antarctic subglacial lakes inventoried as of 2005. After Siegert, M.J., Dowdeswell, J.A., Gorman, M.R. and McIntyre, N.F. (1996). An inventory of Antarctic sub-glacial lakes. *Antarctic Science* 8, 281–286.

previous interglacial periods. The sub-glacial environment has been isolated from the atmosphere and from sunlight for at least 100,000 years. In the total darkness, thousands of meters from sunlight, these micro-organisms rely on energy gained from the oxidation of chemicals or detrital organic matter. A study by Christner et al. (2014) concluded that the microorganisms are a diverse mixture of bacteria and archaea. The latter are one of the most primitive single-cell life forms on Earth. Together, the aquatic microbes in Antarctic subglacial lakes form an ecosystem of producers and consumers. The producers gather chemical energy, and are, in turn, consumed by some of the bacteria.

Current Changes in the Antarctic Ice Sheets

The ice sheets of Antarctica are far from static. Movements of glaciers and ice streams channel flowing ice from the interior to the oceans (Davies, 2018). These ice streams are fed by substantial inland catchment areas (Fig. 15) (Rignot et al., 2011). Fluctuations in the mass of ice sheets over bedrock are caused by differences between net snow accumulation at the surface and melt-water runoff and ice discharge into the ocean. In recent decades, reductions in the thickness and extent of floating ice shelves have disturbed inland ice flow, triggering retreat, acceleration, and drawdown of many ice streams that terminate in the Southern Ocean. The progressive thinning of ice shelves and the retreat of ice shelf margins has led to a progressive draw-down of inland ice, by way of ice streams. It is thought that increased temperatures in the Southern Ocean are the major cause of ice shelf degradation. The most significant losses of ice shelves have been on the Antarctic Peninsula, where there are no ice streams. This is where we can most clearly see the response in the glaciers behind them. They are only just starting to stabilize about 30 years after initial ice-shelf loss. A recent analysis of satellite observations of the changing volume of Antarctic ice cover, combined

Fig. 15 Map showing the ice streams of Antarctica and the velocity of ice movement. Velocity data from Rignot, E., Mouginot, J., Scheuchl, B. (2011). with modeling of its surface mass balance, show that the continent lost 2720 ± 1390 billion tonnes of ice between 1992 and 2017 (Shepherd et al., 2018). This corresponds to an increase in mean sea level of 7.6 ± 3.9 mm (errors are one standard deviation). Over this 24 year interval, ocean-driven melting has caused rates of ice loss from West Antarctica to triple, from 53 ± 29 billion to 159 ± 26 billion tonnes per year. The rate of ice-shelf collapse has increased four-fold during this interval. Ice shelves collapse largely in response to long-term thinning from below, with collapse triggered by hydrofracture from ponded meltwater during warm summers. Under pressure, the ponded water forces new fractures (crevasses) in the glacial ice, creating points of weakness (Fig. 16).

Life in Ice-Free Regions

Ice-free areas cover only one-third of 1% of Antarctica. These rare ice-free areas include nunataks, mountain peaks and other rock formations exposed above a glacier or ice sheet. One of the best known ice-free regions is the Dry Valleys region near McMurdo Station (Fig. 17). Even the few ice-free regions of Antarctica have extremely harsh environments dominated by bitterly cold temperatures and permanently frozen soils (permafrost). However, a very shallow layer of soil thaws during the Antarctic summer (the so-called “active layer”). The growing season in Antarctica, when the soil surface temperature is above freezing and liquid water is available, lasts 25–75 days (Pushkareva et al., 2018). Biological soil crusts (BSCs) are common in this type of environment. These are composed of soil aggregates held together by communities of living bacteria on the surface (Fig. 17). Cyanobacteria are the dominant components of most soil communities in Antarctic BSCs and they are the primary colonizers of poor Antarctic soils. They are able to produce simple sugars through photosynthesis. Cyanobacteria are particularly well adapted to survive in harsh

Fig. 16 Map of major under-ice lakes and streams in Antarctica, highlighting the location of the proposed mantle plume under a dome in Marie Byrd Land, West Antarctica. Image courtesy of NASA-JPL.

and variable conditions. They have developed a wide range of strategies that help them minimize or avoid the harmful effects of harsh environments. One of the secrets of their success in Antarctica is that they exude polymers onto the surface of the cell that protect them from desiccation. They also have pigments that protect them from ultraviolet radiation. They become dormant through the long Antarctic winters. A soil survey in the Sør Rondane Mountains of East Antarctica found 18 different species of cyanobacteria (Pushkareva et al., 2018).

A group of microbial biologists recently discovered a reasonably diverse assemblage of bacteria surviving in this kind of environment. Papale et al. (2018) found more than 50 species of bacteria living in the shallow active layer in an unglaciated region at Edmonson Point, Northern Victoria Land. The bacteria had very small cell sizes ($<0.1 \mu\text{m}^3$), indicating the occurrence of stressed, dormant and/or starved cells. The soil bacteria appeared to be metabolically active, acting as decomposers of organic matter, some of which was transported from coastal or oceanic sources (i.e., bird droppings). These bacteria withstand freezing for perhaps 10–11 months of each year, then become biologically active during the few short weeks of summer when the top layer of soil thaws.

The hyper-arid deserts of the McMurdo Dry Valleys present some of the most extreme dry, cold environments on the planet. In fact the conditions are so extreme that even microbial life struggles to exist on rock surfaces. In these environments, microbes find shelter from desiccating winds by living just below the surface of porous rocks, where they form endolithic microbial communities. These, in fact, are the most widespread life-form in the ice-free areas of Continental Antarctica. Recently, biologists interested in the kind of life forms that could potentially be found on other planets have tested the ability of colonies of the Antarctic black fungus *Cryomyces antarcticus* to survive the extreme low temperatures, hyper-arid, cold, nutrient-poor conditions, and strong UV irradiation found on Mars. The fungal colonies survived more than a year of tests of exposure to space radiation on the International Space Station (Fig. 18) (Selbmann et al., 2018; Onofri et al., 2015).

On the whole, Antarctica is the least biological of all the continents, with more than 99% of the land covered in permanent ice. Thus, the history of scientific research in Antarctica is chiefly a history of geological, geophysical, and glaciological studies. As discussed in this section, the coasts of the continent host a variety of bird and mammal life, but these are essentially marine organisms that visit Antarctic shores to mate, lay eggs, or give birth to live young. They rely exclusively on the biological resources of the sea to feed themselves, for as we have seen, Antarctica itself has none to offer. The human visitors to Antarctica live much as they would have to do on a lunar or Martian colony, except that they can breathe the Antarctic air. They must live in heated shelters, they venture outside in highly protective clothing, and must have all the resources required to sustain life brought in from other countries, except fresh water. The technological advances of the 20th and 21st century have allowed humans a foothold on this continent, and they have performed some prodigious feats of scientific research in spite of working in more-or-less life threatening conditions whenever they were outdoors. In fact, the exploration and scientific investigation of Antarctica has taken hundreds of lives since the beginning of the 20th century, mostly through transportation accidents. The greatest single cause of accidental death has been airplane crashes, which have taken 336 lives. Shipwrecks in Antarctic waters have caused 32 fatalities since 1900, and fires inside research station buildings have taken another five lives.

Fig. 17 Image of the Dry Valleys region of Antarctica, courtesy of the Antarctic Geospatial Information Center.

Looking Toward the Future

Antarctic science has turned out to be much more important than just finding out how much ice covers the bedrock. Antarctic ice cores have yielded the longest unbroken records of terrestrial climate change. Some of the most exciting research has concerned the existence of micro-organismic life in subglacial lakes: archaea and bacteria living in total darkness, deriving chemical energy from minerals and sediments. The discovery of bacteria and fungi living *inside* the surface of rocks has been another startling discovery. Not only do these discoveries enlighten us as to the tenacity and ingenuity of life in this planet's most extreme environments, they also point towards the very real possibility of this kind of life on Mars, or in water beneath the icy surface of moons in this Solar System, such as Saturn's moon Enceladus and Jupiter's moon Europa. Thus Antarctica has become a kind of laboratory to help space scientists understand how extra-terrestrial ice-covered bodies work (Carroll and Lopes, 2018). Hopefully the spirit of international cooperation that was launched in Antarctic will persist in future scientific endeavors in space.

Abstract

Antarctica's contemporary terrestrial biota have adapted to the continent's environmental challenges over many millions of years. It now faces the twin challenges of the multiple aspects of global and regional environmental change and the direct impacts of human presence and activity. Most native terrestrial biota possess wide physiological and ecological flexibility, well beyond the expected scale of environmental change over the next century and, when considered in isolation, are likely to show positive responses to environmental ameliorations, particularly the combination of increased thermal energy and liquid water availability, through increased production, populations, local distribution extent, and community complexity. However, over this timescale other, direct, human impacts on Antarctic terrestrial ecosystems and biodiversity are likely to have greater and negative consequences. Major sources of such impacts are likely to come through physical damage to the limited available area of terrestrial habitats, and the anthropogenic introduction of non-native species, a proportion of which are likely to become invasive and act as ecosystem engineers.

Introduction to Antarctic Biogeography and Biota

Antarctica is a continent of extremes and has long been a source of fascination. In contrast with the Arctic north, which is a relatively small ocean surrounded by large continental landmasses, Antarctica is itself a large continent, roughly twice the area of Australia, lying over the geographical South Pole. It is isolated from the other Southern Hemisphere continents by the vastness of the Southern Ocean (Fig. 1). Antarctica was part of the supercontinent Gondwana and remained at high southern latitudes while the other southern continents moved northwards away from it. Its final links were with Australia and South America, which were broken around 30–35 million years ago. Many tens and hundreds of million years ago, global climates were considerably warmer than now, and Antarctica was not glaciated. Even with its southern position, it hosted temperate and even subtropical vegetation and animals (see Convey et al., 2018 for an overview of Antarctic biological and glacial history).

As the southern continents separated, the formation of a major circumpolar ocean current took place, the Antarctic Circumpolar Current. This, combined with the strong and unobstructed atmospheric circulation that could then develop surrounding the continent and a global trend of decreasing atmospheric carbon dioxide concentration at the time, isolated Antarctica from lower latitudes, leading to cooling and eventually the formation of continental ice sheets in the Miocene. The extent of glaciation has fluctuated widely since the first formation of these ice sheets. In Victoria Land there is fossil evidence for the persistence of tundra-like ecosystems until around 12–13 Ma, and possibly even later in the northern Antarctic Peninsula.

Fig. 1 Map of Antarctica and the Southern Ocean, indicating the complexity of biogeographic regionalisation now appreciated. Continental Antarctic Conservation Biogeographic regions (ACBRs) are indicated as described by Terauds and Lee (2016), along with sub- and peri-Antarctic regions. Reproduced from Chown SL and Convey P (2016) Antarctic entomology. *Annual Review of Entomology* 61: 119–137.

Today, Antarctica is a continent buried in ice, with less than 0.4% of its area ice- or snow-free. Terrestrial ecosystems are mostly limited to ice-free areas, typically including exposed nunataks, cliffs, slopes, boulder and scree fields, and valleys, along with exceptional and unusual geothermal areas (Convey, 2017) (Fig. 2). Conventionally, Antarctic terrestrial habitats and biodiversity include freshwater (lakes, ponds, streams) and snow and ice ecosystems (snow algae, cryoconite). Most Antarctic terrestrial biodiversity develops in coastal regions of the continent, where air temperatures hover close to or just above zero in the summer months and liquid water—the major driver of the continent’s diversity (Convey et al., 2014)—is more predictably available. However, life is present in all ice-free areas of the continent, even on the southern-most nunatak high on the continental ice plateau.

Antarctic Terrestrial Biogeography

In common with most scientific effort on the continent, terrestrial biological research commenced in earnest in the 1960s, although scientific collections had been an important element of most of the exploring expeditions from the early 20th century. Over most of the subsequent 50–60 years, three Antarctic biogeographic zones were generally recognized, the sub-, maritime, and continental Antarctic (e.g., Smith, 1984). Respectively, these zones include (a) a ring of chronically cool, remote and isolated islands at mid to high latitude in the Southern Ocean (ca. 45–54°S), (b) the western Antarctic Peninsula to ca. 73°S along with the Scotia Arc archipelagos of the South Shetland, South Orkney and South Sandwich Islands plus the isolated Bouvetøya and Peter I Øya, and (c) the

Fig. 2 Pictures illustrating typical features of the main Antarctic biogeographical regions. (A) Much of continental Antarctica experiences frigid desert conditions, as here in the Davis Valley, Pensacola Mountains, a “dry valley” at the eastern-most exposure of the Transantarctic Mountains and one of the least biodiverse ecosystems known. (B) Forlidas Pond, also in the Pensacola Mountains, an example of a lake that is almost completely permanently frozen other than a thin layer of hypersaline brine beneath the ice and a seasonal small “moat” of summer meltwater; the pond is surrounded by evidence of ancient lake shorelines and multimillion year-old patterned ground. (C) Inland ice-free ground in the continental Antarctic is typified by remote nunataks and mountain ranges, such as the Behrendt Mountains in Ellsworth Land, surrounded by ice sheets of 1–2 km thickness. (D) Extremely nutrient-enriched ground near vertebrate aggregations may be so polluted by guano that the only visible vegetation is the alga *Prasiola crispa*, as here on Saunders Island, South Sandwich Islands, northern maritime Antarctic. (E and F) Cryptogamic vegetation (mosses, liverworts, lichens, algae) typifies the maritime Antarctic, as here on Robert Island, South Shetland Islands, where some of the most extensive continuous vegetation in the region is found. (G) Most ice-free ground in the maritime Antarctic consists of steep cliffs, with even shallower ground being predominantly ice-scoured rock and periglacial in nature, as here at Evensen Point, Antarctic Peninsula. (H) Lake ecosystems are well-represented on sub-Antarctic South Georgia, as here at Maiviken; lake faunas consist only of invertebrates, although there are two native species of duck. (I and J) With an alpine mountain backbone rising to almost 3000 m, South Georgia is a rugged sub-Antarctic island; milder coastal areas and sheltered northern valleys are densely vegetated, predominantly by tussock and other grasses. (K) Campbell Island, one of the “New Zealand sub-Antarctic islands” illustrates the inclusion of woody bushes in the native vegetation of this milder region. (L) Above the treeline on Isla Navarino, in the Magellanic Sub-Antarctic Ecoregion of Tierra del Fuego, vegetation is dominated by cushion plants, grasses and mosses, many in common with the sub-Antarctic islands. (M) Cool temperate Gough Island, just south of the oceanic Sub-Antarctic Front, hosts forests of the tree *Phylica pubescens*. (N) Just north of the Sub-Antarctic Front and technically humid subtropical, the aptly named Inaccessible Island in the Tristan da Cunha archipelago is ringed by almost impenetrable tussock grass at the base of its cliffs, in common with the islands further south, wherein sub-Antarctic fur seals breed. Fig. 2 (continued).

main body of the Antarctic continent plus the eastern part of the Antarctic Peninsula. Terauds et al. (2012), updated by Terauds and Lee (2016), using multi-layer spatial analyses based on quality-controlled and spatially explicit terrestrial biodiversity data available in the SCAR Antarctic Terrestrial Biodiversity database (www.scar.org/data-products/bio-database/), recognized far greater biogeographic structure in Antarctica than previously thought. As a result, 16 distinct “Antarctic Biogeographic Conservation Regions” (ACBRs) are now recognized within the Antarctic continent and Peninsula (Fig. 1). This analysis did not extend to the sub- or other peri-Antarctic islands, which clearly add further analogous regions. However, the original tripartite formulation still has utility, with ecosystems in each zone sharing important features of environmental conditions, ecosystem structure and overall representation of different biological groups.

Sub-Antarctic

Various broader or narrower definitions of the sub-Antarctic region exist in the literature (see Selkirk, 2007). A “core” sub-Antarctic region can be recognized, defined by the general lack of woody plants (trees and shrubs) and true terrestrial vertebrates. This includes South Georgia, Marion and Prince Edward Islands, the Crozet and Kerguelen archipelagos, Heard and McDonald Islands, and Macquarie Island, with most other than South Georgia and Heard Island being close to or north of the boundary of the Antarctic Circumpolar Current (Fig. 1). These islands have chronically cool climates, with annual temperature variation strongly buffered by the vast expanse of surrounding cold ocean, and much reduced environmental seasonality compared with the Antarctic zones further south.

Further islands and island groups are often described as “sub-Antarctic,” in particular the New Zealand associated Snares, Campbell, Bounty and Chatham Islands, and also the Magellanic sub-Antarctic region of Tierra del Fuego. Some of these (e.g., Diego Ramirez, south of Tierra del Fuego) are colder than some of the core sub-Antarctic islands year-round. Finally, there is biological connectivity, particularly in terms of marine diversity, with the lower latitude cool temperate Falkland Islands and Gough Island, Îles Amsterdam and St. Paul, and even the technically sub-tropical Tristan da Cunha archipelago. The terrestrial diversity of all these latter islands includes groups absent from the core sub-Antarctic.

Maritime Antarctic

This zone experiences strong marine influence at least during the summer months, with the stable Southern Ocean sea temperatures close to the coast, always within a degree or two of freezing, driving the overlying air temperature. About 3% of the area of the Antarctic Peninsula and Scotia Arc archipelagos is ice-free, a somewhat greater proportion than the continent as a whole. Ice-free land is most extensive at low altitude near the coast. While mean air temperatures are just above zero for the short Antarctic summer, those of terrestrial microhabitats can show considerably more variation and higher averages, with dark rock, soil and vegetation habitats, as well as shallow freshwater habitats, absorbing solar energy (Peck et al., 2006). In contrast with a general perception of Antarctica being a frigid desert, precipitation is high in this region, and increasingly falls as rain in the summer months. The South Sandwich Islands, Deception Island in the South Shetland Islands, and Bouvetøya are unusual Antarctic examples of active volcanic islands, and host exceptional and distinctive biological communities on areas of heated ground (Convey et al., 2000) (Fig. 3).

Continental Antarctic

By far the largest of the three conventional biogeographic zones, the continental Antarctic includes all of East Antarctica, the Balleny Islands, all remaining parts of West Antarctica south of the maritime Antarctic, and the eastern side of the Antarctic Peninsula. Ice-free land extent is much more limited—only 0.2 to 0.4% overall—and, excepting the Dry Valley region of Victoria Land, typically consists of nunataks and other small island-like areas of ground that can be extremely isolated. Similar to the maritime Antarctic, there are a number of ice-free coastal oases spread along the East Antarctic coastline. Mean air temperatures are positive for as little as 1 month in coastal oases and never inland, where they rarely if ever become positive even briefly in summer in the latter. Beyond the Antarctic Circle there is extreme seasonality in day length.

Habitats

Across the Antarctic continent and Peninsula most low lying terrestrial habitats experience at least some snow cover for part of the year, buffering them to varying extents from extreme low temperatures. This is not the case for many of the sub-Antarctic and lower latitude islands, which typically have only intermittent snow cover, and then often only at higher altitudes. The extent and depth of vegetation cover, even on colder islands such as South Georgia and Heard Island, means that microhabitat temperatures often remain close to and even above zero, allowing year-round biological activity.

Antarctic soils are poorly developed, lacking the multiple distinct horizons of more familiar lower latitude soils, and generally have low organic content (Thomas et al., 2008). Permafrost and periglacial processes and features are a ubiquitous feature of soils of the maritime and continental Antarctic. However, permafrost is not present on most sub-Antarctic islands, certainly at lower altitudes. True “brown” soils are widespread in the sub-Antarctic, but are only found under larger stands of the two native species

Fig. 3 There are few active geothermal areas within the limited ice-free ground of the Antarctic, but those that exist host exceptional plant and invertebrate communities, with some species only able to survive in the Antarctic because of the permanent source of heat and water, although there are also extremes of chemical stress. (A–C) Lush moss and liverwort communities develop around fumaroles and areas of intensely heated ground within the crater on Bellingshausen Island, South Sandwich Islands; the concentric pattern of vegetation is a function of the different thermal tolerances of the species present. (D) Patches of moss develop along the rim of a small active crater on Candlemas Island, subject to temperature and chemical stresses. (E) Lush vegetation around the mouth of a fumarole on Candlemas Island. (F) Vegetation patches develop around areas of gentler heating on Deception Island, South Shetland Islands, in otherwise largely barren scoria slopes. Photo credits: All photos Peter Convey.

of flowering plants in the maritime Antarctic. The development of deep and extensive peat deposits in wet valleys is a feature of the sub-Antarctic islands. Peat is much more restricted in the maritime Antarctic and differs in comprising mesic moss species whose growth is absorbed into permafrost without decaying, even remaining viable for up to ca. 2000 years (Roads et al., 2014) (Fig. 4).

Terrestrial Biota

Native terrestrial vertebrates are virtually absent from all Antarctic regions, meaning that the fauna is almost entirely invertebrate (Fig. 5). Exceptions are an endemic passerine bird (the South Georgia pipit) and two otherwise South American freshwater ducks on sub-Antarctic South Georgia and/or Kerguelen, and two scavenging sheathbills, one occurring in the maritime Antarctic and

Fig. 4 Moss bank vegetation in the maritime Antarctic. (A) Relatively young *Polytrichum strictum* bank formed on Candlemas Island, South Sandwich Islands, known not to have been present when the islands were surveyed after eruptions in the early 1960s. (B and C) Development of extensive and deep moss banks comprising *P. strictum* and *Chorisodontium aciphyllum* is a feature of the western Antarctic Peninsula and Scotia Arc archipelagos, as here on Signy Island, South Orkney Islands; these banks can be 2 m or more deep, entering permafrost at 20–30 cm depth, and their bases have been dated to be up 5–6000 years old. (D) Ice thinning in recent decades in the maritime Antarctic is re-exposing buried mosses and moss banks: the band of black moss here on Signy Island is recently re-exposed, continuous with the green living moss bank above; in some instances, mosses re-exposed after several hundred years' burial have been viable and shown regrowth. (E) The most southern known *P. strictum* peat bank formation, in Lazarev Bay, northern Alexander Island (69°S); the presence of these banks of around 50 cm depth illustrates the importance of local microclimate, they do not contain permafrost, but have provided records of climate and biological activity over more than the last hundred years. (F) Peat cores and monoliths provide important climate and biological proxies enabling environmental reconstruction, this example is a monolith collected near Volunteer Point in the oceanic cool temperate Falkland Islands. Photo credits: (A, E, F) Peter Convey, (B–D) James Fenton.

South Georgia, and the other endemic to Marion and Prince Edward Islands, both scavenging species largely reliant on marine vertebrate colonies and aggregations. Native terrestrial mammals, reptiles, amphibians and freshwater fish are absent, although anthropogenically introduced mammals and, on some islands, fish have had considerable negative impacts on terrestrial and freshwater ecosystems. Antarctic marine vertebrates (penguins, seabirds, seals) are responsible for considerable transfer of marine-derived nutrients into terrestrial ecosystems, thereby being important drivers of terrestrial diversity and biomass in coastal regions of the sub-, maritime and continental Antarctic (Bokhorst et al., 2019), with this influence extending several hundred kilometers inland in parts of the latter.

Fig. 5 Examples of the terrestrial invertebrate diversity of the Antarctic; arthropods are the largest and most visible members of the terrestrial and freshwater invertebrate community. (A) Aggregation of multiple instars of the oribatid mite *Alaskozetes antarcticus*, with a single individual of the maritime Antarctic endemic midge *Belgica antarctica*, the largest terrestrial invertebrates in the Antarctic continent. (B) An individual of the predatory mesostigmatid mite *Gamasellus racovitzai*, the largest terrestrial predator on the Antarctic continent. (C) The springtail *Cryptopygus antarcticus*, one of

Freshwater ecosystems in the maritime and continental Antarctic zones, and on the colder sub-Antarctic islands like South Georgia, are seasonally or permanently ice-covered. Shallower ponds and streams on the continent freeze to the bottom or cease flowing entirely in the winter months. Only a single river is formally recognized on the Antarctic continent—the Onyx River in the Victoria Land Dry Valleys. Lake ice cover leads to high stability and stratification in the water column, and some continental Antarctic lakes are meromictic. Others become hypersaline through evaporation, at the extreme consisting of a lens of ice overlying a few centimeters of hypersaline brine, such as seen at Forlidas Pond in the Pensacola Mountains. A number of coastal epishelf lakes exist around Antarctica, such as Ablation Lake on Alexander Island, where permanent surface ice covers permits a stable freshwater layer to overlie tidal marine water, with a steep halocline at the boundary between the water masses. Such lakes host entirely independent communities typical of fresh or marine water. Some continental lakes may be hundreds of thousands of years old. Finally, it is now realized that several hundred subglacial lakes exist at the base of the continental ice sheets, some of them forming part of active drainage systems. The largest of these is Lake Vostok, at ca. 200 km long and 500 m deep. The possibility of these lakes containing microbial and even metazoan ecosystems has been a subject of some controversy and is attracting considerable research attention (Pearce, 2009). Sampling these lakes without contamination is challenging.

As with the terrestrial invertebrate fauna, the representation of higher taxonomic groups in the Antarctic flora emphasizes that many groups familiar from lower latitudes are absent (Fig. 6). Restricting consideration to the “core” sub-Antarctic islands, these absentees include trees and other woody plants, other than dwarf-shrub-like rhizomatous herbs (*Acaena*), and the dwarf shrub *Coprosina* on Macquarie Island. There are also no insect-pollinated plant species (with a similar lack of insect pollinators). Smith (1984) provides an accessible and thorough overview of Antarctic floras, although there have been subsequent advances in taxonomy. Monographs of the Antarctic lichen (Øvstedal and Smith, 2001) and bryophyte (Ochyra et al., 2008) floras are available. Trees and shrubs are clearly important elements of communities in the less extreme New Zealand sub-Antarctic islands, the Magellanic sub-Antarctic and the remote cool temperate oceanic islands.

Sub-Antarctic

Other than the few exceptions mentioned above, Antarctic terrestrial faunas are entirely invertebrate (see Convey, 2017 for an overview). Faunas of the sub-Antarctic islands include true insects, with the greatest diversity in the flies (Diptera) and beetles (Coleoptera) and only a few species in other groups (e.g., Lepidoptera, Hymenoptera, Hemiptera) (Chown and Convey, 2016). Other arthropod groups are also present (Aranaea, Isopoda), along with some molluscs and annelid worms. Relatively high diversities are present in groups of micro-arthropods (Acari, Collembola), micro-invertebrates (Nematoda, Tardigrada, Rotifera) and microscopic and polyphyletic Protozoa, although many of these non-charismatic and cryptic groups have received very limited critical attention, particularly in recent years following the advent and rapid expansion of molecular phylogenetic techniques.

Freshwater ecosystems in the sub-Antarctic have very simple structure in comparison with those of lower latitudes, and also in comparison with the Arctic. Freshwater ducks are native on South Georgia and Îles Kerguelen, and their diets include freshwater and terrestrial invertebrates, and even carrion. Native fish are entirely absent, although some have been introduced on Îles Kerguelen. Top predators within the freshwater communities are typically crustaceans, although a single predatory diving beetle plays this role on South Georgia. Faunas otherwise include various Crustacea (cladocerans, copepods, ostracods, anostracans), micro-arthropods, nematodes, tardigrades, rotifers and protozoans.

Flowering plant floras of the different sub-Antarctic islands have affinities with either southern South America, South Africa or New Zealand. In the absence of grazing mammals or birds, there has been exceptional development of large “megaherbs” and tussock grasses, with a suggestion that at least some of these may represent lineages driven from Antarctica itself by the glaciation of the continent (Winkworth et al., 2015). While there is almost complete cover and high vegetation biomass in low altitude coastal regions, at higher altitudes this community is replaced by a cryptogamic flora dominated by mosses and lichens, with many species in common with the flora of the maritime Antarctic.

Maritime Antarctic

In the maritime Antarctic only two native higher insects are present, both chironomid midges (Diptera). As with the sub-Antarctic, communities of mites (Acari) and springtails (Collembola) are present, and micro-invertebrates are also well represented. These again have not been well-studied, although classic, molecular and integrated taxonomic approaches are now starting to demonstrate considerable cryptic speciation in the groups examined. Particular attention has been paid recently

the most common terrestrial arthropods in the maritime Antarctic and parts of the sub-Antarctic. (D) Ground aggregation of the swarming midge *Parochlus steinenii* on the South Shetland Islands, a species that also occurs in the sub-Antarctic and southern South America, and the only flying insect occurring naturally within the Antarctic continent. (E) Adult diving beetle, *Lancetes angusticollis*, the top invertebrate predator within lake ecosystems on sub-Antarctic South Georgia. (F) The tardigrade *Acutuncus antarcticus*, a widespread continental species. (G) A gravid female of the copepod *Boeckella poppei*, a species that unusually occurs across all three of the major Antarctic biogeographic regions as well as in southern South America. Photo credits: (A–C) Elisabeth Biersma, (D) Felipe Simoes, (E) Gonzalo Arriagada Kritzer, (F) Megumu Tsujimoto, (G) Claudia Maturana.

Fig. 6 Illustration of the variety of different Antarctic vegetation. (A) A diverse range of soil fungi are known from Antarctica, but basidiomycete “toadstools” are relatively unusual and limited to warmer microhabitats in the maritime Antarctic (including geothermal habitats), although more widespread in the sub-Antarctic; this example is on Léonie Island, ca. 67°S, almost the furthest south location known. (B and C) Across the continental Antarctic, moss and lichen vegetation development is limited, with small clumps in isolated microhabitats being the typical form found; these examples from Arrival Heights, McMurdo Sound, and Ross Island, Victoria Land. (D) In the maritime Antarctic, as here on Lagoon Island, close to Adelaide Island, visible vegetation is dominated by clump, carpet and turf forming mosses, and distribution strongly influenced by water availability. (E) Only two species of flowering plant, the hairgrass *Deschampsia antarctica* and the pearlwort *Colobanthus quitensis*, occur on the Antarctic continent, both also found on sub-Antarctic South Georgia and in southern and Andean South America; they often grow together as here in Lazarev Bay, Alexander Island. (F) Diverse lichen communities develop on rock faces, boulder and scree slopes and fellfields in the maritime Antarctic; this example from Lagoon Island. (G) Extensive and dense coastal tussock grass is a feature of the natural environment of many sub- and peri-Antarctic islands, as here in East Cumberland Bay, South Georgia. (H) The sub-Antarctic has much greater native flowering plant diversity than the regions further south, with the species *Acaena magellanica* seen here at Husvik, South Georgia, being distributed across most core sub-Antarctic islands as well as in southern South America. (I and J) With more severe conditions rapidly taking over at higher altitude, diverse cryptogamic fellfields rapidly become dominant, as at Bird Island, South Georgia. (K) Dense vegetation, dominated by *Acaena magellanica*, the cushion plant *Azorella selago* and the Kerguelen cabbage *Pringlea antiscorbutica*, on Île Australia, sub-Antarctic Îles Kerguelen. (L) A shallow pond on Île Australia, with aquatic *Ranunculus pseudotrullifolius* surrounded by flowering *Acaena magellanica*. (M) An example from Campbell Island of the “megaherb” vegetation that has evolved on the sub- and milder peri-Antarctic islands in the absence of native vertebrate grazers. Fig. 6 (continued).

to Collembola, identifying considerable intra-specific differentiation and cryptic speciation and providing rapidly strengthening support for the biogeographic regionalisation integral to the recognition of Antarctic Conservation Biogeographic Regions (ACBRs; Terauds et al., 2012). It is likely that application of similar approaches to Acari, Nematoda, Tardigrada and Rotifera will lead to similar outcomes. While invertebrate distributions are strongly limited by the minute extent of ice-free ground, and within that of suitable habitat, population densities are often high, tens of thousands to millions of individuals per square meter; counter to common expectation, such values are comparable with many temperate and tropical ecosystems for these groups. While Antarctic terrestrial food webs have simple structure, the typical trophic functions are represented (producers, consumers, predators, parasites, detritivores), while the overall low diversity makes these systems attractive models within which to study the ecosystem consequences of environmental change. However, there remains a lack of detailed and species-specific autecological studies.

Freshwater communities are similarly of low diversity and complexity. Planktonic herbivores include single copepod (*Boeckella poppei*) and anostracan (*Branchinecta gaini*) species, with predators represented by the copepod *Parabroteas sarsi*. Benthic cladocerans and ostracods are also present, as well as abundant tardigrades, rotifers and nematodes, and microscopic protists. The microbial loop, which consists of phytoplankton, bacteria and protozoans, is functionally very important in maritime and continental Antarctic lakes (Laybourn-Parry, 1997). *Boeckella poppei* poses intriguing biogeographic questions, as it is the only crustacean and indeed only arthropod species of any sort that is thought to occur across all three of the main Antarctic biogeographic zones, as well as extending into southern South America (Maturana et al., 2019).

Maritime Antarctic floras are dominated by cryptogams (bryophytes, lichens, algae) (Smith, 1984). Extensive areas of vegetation, consisting of communities of carpet- and turf-forming mosses, are exclusively coastal and low altitude. At more exposed or extreme sites, fellfield communities develop, consisting of cushion and turf-forming mosses, liverworts and diverse lichens. Only two native flowering plants occur, the hairgrass (*Deschampsia antarctica*) and the pearlwort (*Colobanthus quitensis*). While both only rarely occur at high densities, they are present throughout the maritime Antarctic to southern Marguerite Bay (ca. 69°S), and also occur in parts of the sub-Antarctic, southern South America and at higher altitude in the South American Andes. One feature of the typical cryptogamic vegetation is that it is fragile and easily physically damaged. Therefore, areas close to vertebrate concentrations where there is a lot of trampling are often dominated by the foliose alga, *Prasiola crispa*. Similarly, careless human activity on foot or using vehicles can lead to long-term damage to this fragile vegetation.

Continental Antarctic

There are no insects in the continental Antarctic. Similar overall diversities of Acari, Collembola and Nematoda are present to the maritime Antarctic (Convey, 2017), often with congeneric species and again noting the caveat that modern molecular approaches are likely to reveal considerable increases in these diversities. The continental Antarctic includes multiple ACBRs, with species endemism within particular regions being a common feature (e.g., Adams et al., 2006). Even with current levels of diversity knowledge, a particularly striking feature in comparing maritime and continental Antarctic diversity is that, at species level, no or almost no species are shared between the two zones in the Acari, Collembola and Nematoda. This is an important and ancient biogeographic feature and led Chown and Convey (2007) to erect the Gressitt Line across the base of the Antarctic Peninsula, analogous to the widely known Wallace Line in south-east Asia. The continental Antarctic includes some of the simplest faunal communities known on Earth.

As with the maritime Antarctic, continental Antarctic vegetation is cryptogamic, although lichens dominate. Around 25 bryophytes occur in this zone, compared with ca. 110 in the maritime Antarctic, with greatest community development in the coastal oases. No flowering plants are present.

Microbial Systems

Perhaps more than any other continent, microbial groups dominate Antarctic terrestrial (including snow and ice) ecosystems and the functions and services they provide (Cavicchioli, 2015; Chown et al., 2015), as primary producers, decomposers, and vital in primary colonization and soil stabilization. Modern molecular techniques now confirm that Antarctic microbial and viral communities contain far higher diversity than previously suspected, in contrast with the trend for multicellular organisms (Cary et al., 2010; Aguirre de Cárcer et al., 2015). In some of the most extreme environments, microbial life retreats to endolithic habitats, existing within tiny fissures open to the rock surface, or between crystals within the rock matrix. Such habitats are considered as one limit to life on Earth and are used as model systems in exobiological research (Fig. 7).

Antiquity of the Antarctic Terrestrial Biota

Overall similarity is clear between the invertebrate and plant communities of both polar regions (the dominance of Acari, Collembola, other micro-invertebrates and cryptogamic flora). Indeed, amongst microbial groups and mosses in particular, there are significant proportions of truly bipolar or amphitropical species (Biersma et al., 2017), reflecting the ability of these groups to disperse widely using microscopic spores or other propagules. However, even in these groups, as well as in the various invertebrate groups

Fig. 7 Microbial ecosystems are dominant across much of Antarctica. (A) Pieces of cyanobacterial mat detached from a continental Antarctic lake benthos become entrapped in permanent lake ice, moving slowly towards the surface in their own private melt pool over a few weeks each summer. (B) Trapped gas bubbles in the ice of permanently frozen lakes and over seasonal moats along the edge of glaciers, indicate active microbial life beneath. (C) Cryoconite “holes” develop where dark mineral debris initially accumulates in small depressions on glacier surfaces, absorbing solar energy and melting to form a small pool within which microbial and micro-invertebrate communities live. (D) An unusual example of extensive dried cryptobiotic cyanobacterial mats formed in an area very occasionally flooded by meltwater. (E) Endolithic microbial life within the crystal matrix of a sandstone rock, showing a black pigmented fungal layer, a white non-pigmented layer of fungal hyphae, and a green layer of photosynthetic algae. (F) Rich snow algal communities develop in coastal regions especially in the maritime Antarctic, where water is present in the snowpack during the summer, and nutrient input is received from surrounding marine vertebrate aggregations. (G) The foliose alga *Prasiola crispa* forms seasonally extensive carpets in areas receiving nutrient enrichment from neighboring vertebrate colonies, being able to thrive in higher concentrations than most Antarctic vegetation. (H) Extensive cyanobacterial mats can form in freshwaters, even at close to freezing temperatures. (I) Intense biological activity is apparent in flooded mixed communities of moss, cyanobacteria and algae. Fig. 7 (continued).

typical of the Antarctic, considerable species-level endemism is documented (Pugh and Convey, 2008). These levels approach 100% in groups such as Nematoda, Acari and Collembola.

Over the last two decades, rapid advances in classical biogeographic and molecular phylogeographic research have led to a paradigm change in our understanding of the origin and antiquity of the Antarctic terrestrial biota (Convey et al., 2008). Studies carried out across all ice-free regions of the continent, and all the major terrestrial taxonomic groups, have confirmed that long-term presence in these regions is the norm, requiring persistence of both the organisms and terrestrial habitats through the multiple cycles of glaciation Antarctica has experienced (see Convey et al., 2020, for comprehensive review). Some phylogeographic studies have identified signals of persistence since the final breakup of Gondwana and separation of Antarctica. Others have identified a range of dates between the late Pleistocene and early Miocene, with this remaining a rapidly moving field of research. The overall antiquity of the terrestrial biota, combined with high levels of endemism and strong regionalisation, provide an important foundation element of the recognition of the ACBRs as described above, as well as emphasizing the high conservation value of the Antarctic terrestrial biota, and the governance challenges this presents to the signatory nations of the Antarctic Treaty (Chown et al., 2015, 2017).

Antarctic Environmental Change

The world's polar regions are facing some of the most rapid rates of warming and other environmental changes seen globally, through a process known as "polar amplification." In Antarctica this applies particularly to the Antarctic Peninsula and Scotia

Arc, which have been one of the three most rapidly warming regions globally, although most of the Antarctic continent has to date been protected from the effects of global warming (Convey and Peck, 2019). Over the last two decades the Antarctic Peninsula warming trend has paused, thought to be a result of natural variation, although it is expected to resume and, by 2100, the entire continent is expected to be similarly affected. Even so, temperatures away from the continental coastline will remain well below zero, and this is not likely to lead to biological impacts. However, near the coast, and particularly in the maritime Antarctic, mean air temperatures are already slightly positive. Here, warming is of greater biological significance, providing extra energy, longer seasons, and increased melt and ice-free area (Convey and Peck, 2019). Environmental change involves multiple variables, with precipitation and liquid water availability and, conversely, desiccation, being of great significance to biology (Convey et al., 2014). Several sub-Antarctic islands show increasingly strong signs of biological impacts from reduced precipitation and desiccation. In the maritime Antarctic, conversely, precipitation is both increasing and, during the summer months, falling as rain rather than snow. Antarctica was also where the stratospheric ozone hole was discovered, a further consequence of atmospheric pollution, generating concern about the harmful effects of ultraviolet-B radiation to biological systems.

Antarctic lakes are particularly sensitive to warming, even magnifying the already rapid rates recorded in air temperature (Quayle et al., 2002). Warming and changes in precipitation in the maritime Antarctic, in combination with changing marine vertebrate distributions and influences, lead to changes in biological production, including eutrophication, and water column mixing. Continental Antarctic limnological studies have identified changes in other indicators, such as drier conditions and evaporation leading to increased salinity associated with changes in prevailing winds. Similarly, drier conditions in parts of the continental Antarctic coastline are also implicated by changing patterns of moss distribution and health (Robinson et al., 2018).

Biological Responses to Change in Antarctica

Natural Ecosystems

The sensitivity of Antarctic terrestrial ecosystems to change has long been recognized (Convey and Peck, 2019). However, responses of these ecosystems to warming may not be negative, as is often generally assumed to be the case elsewhere. Noting that the currently biodiverse parts of the maritime Antarctic in particular, but also coastal regions of the continental Antarctic, already experience positive temperatures especially at microhabitat scale, warming will lead to more energy being available to support activity of biota. Increased snow and ice melt, as well as precipitation as rain, increases the availability of liquid water—the major driver of Antarctic diversity—as well as expanding the area of ice-free ground available. Reduction in the limits imposed by low temperature and desiccation will generally result in greater productivity, population growth and expanded distributions at local scale. However, specific outcomes will be influenced by local features. Should water supply from snowmelt or other sources be exhausted then local biological communities will face greater stress. Changes in nutrient supply can also be important. Nitrogen provided by marine vertebrates is another important driver of terrestrial diversity (Bokhorst et al., 2019) and, thus, changes in vertebrate distributions driven by environmental change should lead to consequential changes in the distribution of this diversity. Similarly, large changes in key ecosystem services such as decomposition can be caused by the colonization of new community members, with the known examples to date being associated with human introduction of non-native species. In maritime Antarctic vegetation communities, increased nutrient availability is predicted to be advantageous for stronger competitors for nitrogen.

Much of terrestrial Antarctica is characterized by physical isolation and strong barriers to dispersal between individual “islands” of terrestrial habitat across hostile sea or ice. If warming continues unabated, current trends of ice and snow recession are predicted to lead to a 300% increase in ice-free area in the Antarctic Peninsula region (although this reduces to 25% across the entire continent) (Lee et al., 2017). In the former in particular, this increase will result in the coalescing of currently isolated areas of ground, bringing the potential for genetic homogenization and irreversible loss of genetic diversity (Chown and Convey, 2007) and providing a major conservation challenge. An analogous diversity challenge is posed by human-assisted transfer between different isolated populations of native biota.

A predicted consequence of environmental change globally is that species distributions will change, and that currently non-native species will arrive in previously isolated areas. Throughout the Antarctic, one important isolating factor or barrier is that of the environmental stresses that must be faced both during transfer and on arrival at a potentially colonisable location. Where environmental change reduces these barriers, even in the absence of human assistance it is likely to increase the chance of transfer and establishment.

In concert with this, the balance between abiotic and biotic drivers of diversity is likely to change, with the latter becoming more important, such as competition, herbivory and predation. Native maritime and continental Antarctic biota are generally described as “adversity selected,” investing considerable resources in strategies permitting survival of abiotic stress at the expense of poor competitive ability (Convey, 1996). Further, while biotic interactions are clearly greater on the sub-Antarctic islands, predation is a weak force in the absence of most familiar groups of invertebrate predators (e.g., spiders other than linyphiid “money spiders,” carabid beetles, hymenopterans). Thus, native invertebrate communities across all three Antarctic biogeographic zones are vulnerable to the arrival of stronger competitors, as already demonstrated by the anthropogenic introduction of aggressively predatory carabid beetles to sub-Antarctic South Georgia and Îles Kerguelen (Convey and Peck, 2019) (Fig. 8).

Fig. 8 Direct human impacts on Antarctic terrestrial ecosystems come in a number of forms, the most significant of which include the introduction of non-native species and use change through the construction of stations and facilities, and long-lasting damage to fragile ecosystems. (A) The chironomid midge *Eretmoptera murphyi* is endemic to sub-Antarctic South Georgia but was introduced to maritime Antarctic Signy Island in the 1960s, where it is now spreading rapidly and can lead to an order of magnitude increase in peat decomposition. (B) Predatory carabid beetles have been introduced to sub-Antarctic South Georgia (two species) and Îles Kerguelen; as an entirely new guild of aggressive predators for these islands, the native terrestrial invertebrate community has no defense against them. (C) The trichocerid fly *Trichocera maculipennis* was introduced to King George Island, South Shetland Islands in the late 2000s; in terms of physiology and diet this northern boreal detritivore is well pre-adapted to the maritime Antarctic, and appears to be spreading rapidly on the island, including crossing glacial barriers. (D) The hoverfly *Eristalis croceimaculata* was first noted on South Georgia in the mid-2000s, along with the blowfly *Calliphora vicina*; adults of both species are plant pollinators, a function not represented in the native invertebrate community. While the native flora is wind- or self-pollinated, a number of non-native species, such as the dandelion *Taraxacum officinale*, can be insect pollinated, which for some will lead to a step-change in their potential reproduction and dispersal. (E) The non-native grass *Poa annua* occurs on many sub-Antarctic islands; on South Georgia it has spread to completely carpet valley floors around sites of previous whaling activity. (F) *Nassauvia magellanica* is a native montane species occurring in Tierra del Fuego that was temporarily established before eradication close to the historic Whalers Bay site on Deception Island, South Shetland Islands. (G) Large decaying industrial sites, such as the Husvik whaling station on South Georgia abandoned in the 1960s, continue to be a largely uncontrolled source of debris and pollution into the local environment. (H) Grytviken whaling station on South Georgia has been partially remediated and conserved, although its overall footprint remains large, and it is now a very popular tourist visitor site. (I) Whalers Bay on Deception Island includes both the remains of a 1930s whaling station, and of a United Kingdom research station abandoned after the island erupted in the late 1960s; although now a historic site, the remaining buildings and facilities are in poor condition and much dispersed debris is present. (J) Abandoned amphibious vehicles around stations on the Fildes Peninsula,

Surprisingly few studies of biological responses to change have been published from natural Antarctic terrestrial ecosystems. There has been a focus on studies of population increases in the two native flowering plants of the maritime Antarctic (Cannone et al., 2016), although this often results in an inaccurate statement that these species have expanded their distributions southwards, which is not the case. There is increasing evidence that terrestrial invertebrates are sensitive to the magnitude of environmental changes being seen, including extreme events. While there is considerable media reference to the “greening of Antarctica” through expansion of the native vegetation communities and rapid colonization of new ice-free areas, only two robust studies are currently available, both from the maritime Antarctic, for mosses (Cannone et al., 2017) and lichens (Sancho et al., 2017).

The combination of increased spatial resolution in future climate models for parts of Antarctica and detailed knowledge of ecophysiological and microclimatic requirements of individual species has facilitated the application of distribution modeling approaches to both native and non-native species in Antarctica. For example, the native dipteran *Parochlus steinenii* is currently restricted to the maritime Antarctic South Shetland Islands. However under both the IPCC RCP4.5 and 8.5 (the latter being “business as usual”) scenarios the species could occupy habitats much further south along both east and west coasts of the Antarctic Peninsula, and even parts of the East Antarctic coastline given transfer opportunity (Contador et al., 2020). Similarly, the non-native midge, *Eretmoptera murphyi*, a native endemic of sub-Antarctic South Georgia that was accidentally introduced to Signy Island in the maritime Antarctic in the 1960s, is now rapidly expanding its local distribution on the island. Future distribution modeling confirms the likelihood of further considerable distribution expansion on Signy, and that the species is capable of establishing throughout the western Antarctic Peninsula (Perterra et al., 2019). A similar outcome has been reported for the invasive grass *Poa annua*, which has been established on King George Island (South Shetland Islands) for around 40 years and has the potential to spread much further south.

Environmental Manipulation as a Proxy for Climate Change

Long-term field manipulation studies attempting to mimic some of the predictions of climate change models have been an important experimental approach to testing the predicted consequences of changes in environmental conditions for individual species and communities in the Antarctic (reviewed by Bokhorst et al., 2013). Early studies provided very unrealistic manipulations, and problems have not been entirely resolved even with advances in techniques, as inevitably all methodologies affect multiple environmental variables, and rarely provide a good representation of predicted changes over the annual cycle, in some cases even being opposite to the expected changes. Newsham and Robinson (2009), in a meta-analysis of field studies mimicking predicted ozone hole impacts on ultra-violet radiation exposure, found little consistency in the effects obtained. Despite the methodological limitations, even the early warming manipulation studies found that typical maritime Antarctic terrestrial communities responded rapidly with increased biomass, population densities and ground cover. More recent studies with greater replication, more realistic manipulations and multivariate approaches, and accurate micro-environmental monitoring have given these findings greater strength.

Other Direct Human Impacts

Historical and contemporary human activity in Antarctica have posed threats to terrestrial ecosystems and diversity distinct from those directly associated with climate change (Fig. 8). Historically, the main onshore industrial activities in the sub- and maritime Antarctic were associated with the exploitation of, first, fur seals and, later, the great whales. The ongoing impacts on land are mostly focused around the remains of whaling stations, including some major industrial sites such as Leith Harbor on South Georgia. Although ecological impacts during the times of site occupation went undocumented, the physical extent of some of these stations inevitably means that very large areas of native habitat were destroyed, as well as being subjected to extensive pollution. Two such stations, Grytviken (South Georgia) and Whaler’s Bay (Deception Island), have been stabilized or restored, with some effort at pollution remediation. These are now historical monuments, and popular visitor sites for the increasing Antarctic tourism industry. However, other sites have neither been maintained nor cleaned up, and continue to suffer from increasingly dispersed debris and pollution. Another incidental consequence of these historic marine industries for the sub-Antarctic islands, along with accidental shipwrecks, was the introduction (both inadvertent and deliberate) of around half of the non-native species now known from these islands (Convey and Lebouvier, 2009). This is also the case for the lower latitude peri-Antarctic islands with, for instance, an estimate from South Atlantic Gough Island that, on average, every second ship visit over the history of human contact with the island has resulted in one new non-native species establishment.

King George Island, the densest concentration of international research stations in Antarctica as well as a tourist visitor site and entry point, shed debris into the natural environment. (K) Direct human impacts, such as these vehicle tracks on the Fildes Peninsula, easily damage the delicate vegetation and soil surface and take many years to recover; pollution from unsuitably stored fuel and waste is similarly hard if not impossible to remediate. (L) The American McMurdo Station on Ross Island is the largest operational station in Antarctica, accommodating over 1000 personnel in the summer; the station footprint occupies much of the available ice-free area on southern Ross Island, destroying the original sparse terrestrial habitats. Photo credits: All photos Peter Convey.

Fig. 8 (continued).

For practical reasons of accessibility and logistic simplicity, most contemporary human activity is concentrated on the small proportion of the continent that is ice-free. Most research stations and visitor sites are therefore located at or near the coast, in areas where terrestrial ecosystems are most developed and biodiversity greatest, as well as where marine vertebrate colonies are found. In reality, there is already considerable competition for the very limited ice-free land, a large proportion of which is already impacted by human activity ([Chown and Brooks, 2019](#)).

All types of transport and infrastructure used in Antarctica create detectable chemical pollution. They can also lead to local dispersal of dust and can damage soil surfaces, vegetation and freshwater ecosystems ([Bargagli, 2005](#)). The potential is not limited to heavier vehicles and major constructions—even a single person's footfall can compress soil, damage vegetation and measurably alter invertebrate community structure, with recovery taking many decades at least.

Non-native Species

A specific and fundamentally important direct human impact affecting biodiversity in parts of Antarctica already and, without effective regulation, into the future, is that of the human-assisted movement of non-native species, followed by their establishment. This applies both to movement of species from other regions beyond the Antarctic itself ([Frenot et al., 2005](#)) and to movement of species

native to one region of Antarctica to other regions where they are not native (Hughes et al., 2019). Human assistance enables organisms to overcome the environmental and transfer time barriers that otherwise protect Antarctica from colonizing organisms. While dispersal is a natural process, and few studies have documented the frequencies of natural and anthropogenic colonization events, data from some sub-Antarctic Marion Island and cool temperate Gough Island suggest that the human-assisted route has resulted in at least two orders of magnitude more establishment events since these islands' discovery. Furthermore, there are no known examples of species becoming established in the maritime or continental Antarctic since the initiation of human contact with them, while human-assisted establishment in the maritime Antarctic is increasing.

The majority of non-native species that have become established in the Antarctic to date are found on the various sub-Antarctic islands, with well over 200 species known to date virtually all of which are most likely linked with either national Antarctic operations or the preceding whaling and sealing industries (Frenot et al., 2005). Some aggressively invasive non-native species can be particularly significant, even acting as ecosystem engineers, through introducing new ecological guilds and functions that can lead to step changes in ecosystem services. Historical introductions of grazing and predatory vertebrates to most sub-Antarctic islands clearly had major destructive impacts on both their terrestrial ecosystems and on breeding marine birds. Whilst some have been eradicated in expensive and logistically demanding operations, sometimes with unpredicted consequences, many remain. However, of particular and urgent contemporary concern as noted above, the introduction of new guilds of invertebrate predators to some sub-Antarctic islands raises the very real threat of extinction of some native endemic invertebrate species, with "strict" terrestrial diversity to date receiving insufficient attention in sub-Antarctic conservation decision making.

It is clear from the existing record of establishment that many species that are not native to Antarctica are capable of surviving and establishing in Antarctic terrestrial habitats if presented with the opportunity to make the transfer into the region. This is particularly the case for the sub-Antarctic (and lower latitude peri-Antarctic) region, but also applies to the maritime Antarctic and in a few instances the continental Antarctic. The risk of microbial introductions has also been recognized, although few specific studies are available. Risk assessments have identified a number of species or groups as being of particularly high risk of establishment in the coming decades (Hughes et al., 2020), and some have already been confirmed as new arrivals on Deception Island in the South Shetland Islands, a geothermally active and highly visited location thought to be one of the most vulnerable to invasions in the Antarctic. As noted earlier, future distribution modeling studies emphasize that, under current regional climate change scenarios, both native and existing non-native species can be expected to considerably expand their distributions within Antarctica. There is also the realization that synergy between climate similarity and human connectivity (through logistic or tourism operations) further compounds the risk of human-assisted transfer (Hughes et al., 2019).

Concluding Thoughts

Antarctic terrestrial ecosystems and biodiversity today face two distinct but interwoven challenges. First, from the multifaceted elements of global and regional environmental change and, second from the direct impacts of human activity at more local scale within the different regions of Antarctica. Indeed, while climate change is one of the greatest overall challenges facing human society today, on a 21st century timescale it may not lead to widespread negative consequences for Antarctic terrestrial ecosystems that are generally observed or expected elsewhere. Rather, direct consequences of human activity, particularly, development and human activity on land and biological invasions, stand to have far greater impacts on this timescale on Antarctic ecosystems terrestrial ecosystems than climate change itself.

Addressing global climate change is beyond the Antarctic community alone, although it is appropriate to note that the majority of signatory nations to the Antarctic Treaty are also signatories to or engaged in the major global conservation or climate change conventions. In principle, the governance mechanisms are already in place within the Antarctic Treaty System to facilitate appropriate action being taken to control and mitigate the direct impacts of human activity, and to take appropriate action to properly protect Antarctic ecosystems and biodiversity (Chown et al., 2017; Convey and Peck, 2019), and the same is the case for the nationally-administered sub-Antarctic islands. Clear and actioned commitment to continent-wide biodiversity and ecosystem monitoring programmes is required from national operators and funding agencies. These must be appropriately funded and resourced in terms of expertise. Wide education programmes are also required within national operator programmes and tourist operations to ensure clear awareness of the dangers of direct human impacts, and engagement with robust biosecurity measures to minimize the risk of further biological introductions.

Abstract

Nearly one third of the Earth's terrestrial surface are covered by forests of some type, the world's largest terrestrial biome. Forests collectively cleanse the air we breathe; purify our drinking water; play a vital role in regulating regional and global climatic processes; support at least half of all terrestrial species on Earth, especially in the tropics; and provide economic, spiritual, and cultural benefits for millions of people worldwide. Global rates of deforestation and forest degradation have slowed recently based on country-specific reporting overseen by the Food and Agriculture Organization. However, the alarming loss of primary (unlogged) forests remains a global concern (e.g., Global Forest Watch). Gains in forest cover from tree planting do not offset losses. Thus, international initiatives (e.g., UN Sustainability Goals and REDD+ Programme, Convention on Biological Diversity, Paris Climate Agreement) along with national/regional conservation need to protect remaining primary forests and intact forest landscapes while restoring primary forests through "proforestation."

What is a Forest (Definitions and Perspectives Matter)?

A forest is one of those places that you just know you are in when you see it, hike in it, experience all its magnificence, and interact with the constituent parts. But we each see the forest the way we want. Some see it only for the trees, others as an intricate-web- and way-of life.

A forester sees a crop of trees to be "harvested" when the rate of return on investment is optimized. Trees planted in neatly spaced rows (like corn fields), grow money for the owner over time, but lack the structural complexity and biodiversity of "natural forests" (Fig. 1). An ecologist sees a dynamic "self-willed" ecosystem where the sum-of-the ecosystem parts (native species, processes, functions—also known as integrity) is greater than the whole. Indigenous peoples derive sustenance, medicines, food and shelter, and deep-rooted, long-established cultural and spiritual connections to the forest. Their survival depends on the forest.

All told some 800 (<http://www.terisas.ac.in/mct/pdf/assignment/VENKATESWARLU.pdf>) to 1500 (Lund, 2018) forest definitions are used throughout the world, encompassing a range of utilitarian, indigenous, biodiversity, ecosystem and climate change perspectives (Chazdon et al., 2016).

Wikipedia defines a forest as a large area generally dominated by trees consisting of such distinguishing factors as tree density, tree height, land use, legal standing and ecological function (https://en.wikipedia.org/wiki/Forest#cite_note-1).

The Food and Agriculture Organization (FAO) of the United Nations, which oversees the tracking of forest cover by some 163 countries and territories through its Forest Resource Assessments (FRA), has its own definitions. FAO (2015) groups forests into categories that can then be compared with more ecologically based ones (Table 1). Also see Keenan et al. (2015) for limitations of the FAO definitions and related FRA forest loss/gain inventories by reporting countries.

Forests are distinguishable from each other based on classification schemes of various resolution, stepping down from global to local. For instance, using a life zone classification (i.e., Holdridge), forests can be arranged along a three-dimensional axis according to differences in climate, latitude, and altitude (see forest hexagons on the right side of Fig. 2). This classification uses five global forest biomes: boreal (northern most latitudes), cool temperate (high latitudes), warm temperate (mid latitudes), subtropical (lower latitudes), and tropical (equatorial). Within biomes, forests can be arranged by ecoregions—large land masses having similar vegetation, climate, and species assemblages (for an excellent mapped based resource of ecoregions of the world see, <https://ecoregions2017.appspot.com/>).

At finer resolution, potential natural vegetation within a forested region is diagnostic (e.g., Olympic Peninsula, Washington; <https://www.sciencebase.gov/catalog/item/4ffaff70e4b0c15d5ce9fae2>).

Fig. 1 (A) *Radiata* pine plantation, and (B) wet sclerophyll (hard leaved) forest dominated by Mountain ash (*Eucalyptus regnans*) as seen from a canopy tower, New South Wales, Australia. Photo: D. DellaSala.

At the individual stand or site level, forests are defined by species composition, structure (canopy height, dead trees, logs, shrubs), and function (the inner workings of a forest) (Fig. 3).

Land-use features also are diagnostic of the differences in forest quality. For instance, contrast primary (i.e., no evidence of industrial activities) vs. logged (Figs. 4 and 5), and intact forest landscape (e.g., see www.intactforests.org) vs. fragmented (broken apart by human activities) (Figs. 6 and 7).

Where Do Forests Occur?

We live on a green planet; forests, the dominant terrestrial biome, represent ~30% of the terrestrial surface. Currently, about ~3.7 billion ha are considered “natural forests” by FAO (2016), although see Keenan et al. (2015) for data limitations along with a lower bound on global forest estimates in Hansen et al. (2010, 2013) using stricter definitions and satellite tracking. Forests are found on every continent except for Antarctica (Fig. 8). Most of the global forest area (using FAO definitions) is tropical (44%), followed by temperate (26%), boreal (22%), and subtropical (8%) (Keenan et al., 2015).

Table 1 FAO (2015) definition of forests compared to ecologically based approaches

FAO (2015) category	FAO (2015) definition	Limitations/ecological suggestions
Forest	Land spanning >0.5 ha, trees >5 m tall, canopy cover >10%, or trees able to reach these thresholds in situ. Areas temporarily unstocked due to clear-cutting but expected to regenerate within 5 years to reach the criteria. Forest roads, firebreaks and other small open areas; national parks, nature reserves, other protected areas such as environmental, scientific, historical, cultural or spiritual interest. Windbreaks, shelterbelts and corridors of trees with an area > 0.5 ha and > 20 m wide. Abandoned shifting cultivation with regeneration of trees that have, or are expected to reach the forest criteria. Mangroves in tidal zones, rubberwood, cork oak and Christmas tree plantations, bamboo and palms.	Includes forests with varied human activities based on minimum tree cover (e.g., Christmas tree plantations, forests in national parks). Needs to address ecological integrity (native species, processes, functions) and forest quality indicators (e.g., using higher levels of forest cover, e.g., >25%)
Primary forest	Naturally regenerated forest of native species, with no clearly visible indications of human activities and ecological processes are not significantly disturbed. Natural forest dynamics, natural tree species composition, dead wood, natural age structure and natural regeneration processes; large enough to maintain natural characteristics; no known significant human intervention or the last significant human intervention was long enough ago to have allowed the natural species composition and processes to have become re-established.	Can be improved (see Fig. 3). Many nations lack the resources to report this category to the FAO and thus there are data quality problems (see Keenan et al., 2015). Importantly, the Convention on Biological Diversity COP 14 recently adopted a resolution stating the importance of primary forests and ecological integrity. Primary forests should be the reference or baseline for comparisons to all other forest types because of superior ecological integrity (see Mackey et al., 2014; Kormos et al., 2017).
Other naturally regenerated forest	Clear visible signs of human activities: selectively logged; regenerating following agricultural land use; recovering from human-induced fires; mix of naturally regenerated trees and planted/seeded trees; naturally regenerated trees >50% of growing stock at stand maturity.	Could be improved by attention to native species composition, age class distributions, forest structures (especially large live and dead trees/down wood), and ecosystem processes. In the tropics, selective logging results in loss of native species, especially endemics (see Zimmerman and Kormos, 2012). Lower integrity compared to primary forest.
Other naturally regenerated forest of naturalized introduced species	Predominantly naturalized introduced species: trees spread and multiply by natural regeneration and are well established, acclimatized for several years and are an integral part of a region's flora. Specifically excludes invasive species.	Could be improved by attention to native species composition, age class distributions, forest structures (especially large live and dead trees/down wood), and ecosystem processes. Lower integrity compared to primary forests.
Planted forest	Trees established through planting and/or deliberate seeding expected to constitute >50% of the growing stock at maturity. Coppice from trees originally planted or seeded; rubberwood; cork oak and Christmas tree plantations. Excludes self-sown trees of introduced species.	By some definitions, this is not even a forest (see DellaSala in this volume). Lower integrity compared to primary forest.
Planted forest of introduced species	Planted/seeded trees predominantly introduced species expected to constitute >50% of the growing stock at maturity.	By some definitions, this is not even a forest (see DellaSala in this volume). Lowest integrity compared to primary forest.
Mangroves	Area of forest and other wooded land with mangrove vegetation	Could also include all wetland forest types—e.g., bogs, swamps, bottomland hardwoods, riparian areas

What Do We Get From Forests (Biodiversity and Ecosystem Services)?

Ecosystem Services

Forests are the most biodiverse terrestrial ecosystems on the planet with half of the known terrestrial species in tropical rainforests alone that cover just under 2% of the Earth's land mass (<https://rainforests.mongabay.com/0301.htm>). Forest biodiversity is essential for maintaining myriad ecosystem services upon which humanity depends (Brockerhoff et al., 2017). In general, forests:

- Cleanse the air we breathe;
- Regulate the global and regional climate;
- Purify drinking water;
- Perform pollination services;

Fig. 2 Holdridge life zones https://en.wikipedia.org/wiki/Holdridge_life_zones. file:///C:/Users/Greens%20Bushwackers/Downloads/Lifezones_Pengo.svg.

- Provide migratory and overwinter sites for countless wildlife (Fig. 9); and
- A source of income, sustenance (food and spirituality), phytochemical medicinals, recreation, and a way of life for millions of people (among myriad other services).

World-wide forests currently absorb some 9 billion tons of CO₂ per year, equivalent to ~one-third the total fossil fuel emissions annually (Pan et al., 2011). However, the global forest sink is limited and can switch to a source of emissions due to drought stress and increases in tree mortality from uncharacteristic wildfires (e.g., tropics) and logging-related losses (see below).

Notably, tropical rainforests play a critical role in regulating climatic processes via evapotranspiration and the hydrological cycle (<https://rainforests.mongabay.com/0906.htm>). In the Amazon, rainforests generate over 50% of annual rainfall through forest-climate feedbacks (dubbed “rivers of the air”). When these forests are cut down, rainfall patterns can change (e.g., droughts related to intensively logged Amazonia).

In boreal forests, with significant snow cover, increases in surface reflectivity (albedo) due to natural disturbances (wildfires, insect outbreaks) can have regional cooling effects (<https://today.oregonstate.edu/archives/2011/oct/%E2%80%99Calbedo-effect%E2%80%99D-forest-disturbances-can-cause-added-warming-bonus-cooling>). By contrast, in large clearcuts, where the surface is exposed and ground unusually darkened, albedo decreases and this can magnify warming. On a global scale; however, warming due to the buildup of greenhouse gases is a much larger climate forcing than changes in regional albedo effects.

Canada’s boreal forests contain ~one-fourth of the world’s total wetlands and freshwater systems critically important to migratory birds and the flow of water into polar regions for ice formation (<https://www.borealbirds.org/boreal-forest>). The region’s wetlands and peat bogs store the equivalent of some 25 years of global emissions (<http://www.borealscience.org/wp-content/uploads/2012/06/report-forestofblue.pdf>).

Wood Fiber and Fuel

Nearly one-third of the world’s forests are designated primarily for production, more than half of this is distributed in high- vs. 8% low-income countries (FAO, 2016). According to FAO (2016), ~3 billion m³ of wood was removed globally in 2011, ~0.6% of the total “growing stock.” About half of the total wood removals are for fuel with low-income countries removing most of this share. During this time, the forest sector contributed ~\$600 billion to the global Gross Domestic Product (GDP) with forestry and logging representing nearly 20% of the total distributed, in part, among high- (41%) vs. low (5%) income-countries (FAO, 2016). Some 12.7 million people were employed in forestry and logging with nearly 80% of these jobs in Asia alone (mainly Bangladesh, China, India; FAO, 2016).

Fig. 3 (A) Cartoon illustration of forest composition, structure, and ecosystem processes. Composition: A-I represent different native species; structure: represented by the contribution of vegetation layering #1, #4 snags, #5 down logs; processes represented by below-ground connections such as mycorrhizae #2, avian predation, pollination, seed dispersal #3; nutrient cycling #6; herbivory #7, and evapotranspiration/hydrological cycle #8. (B) Stand level features of primary, inland rainforest, British Columbia (photo: D. DellaSala). This forest is dominated by western red cedar (*Thuja plicata*) and western hemlock (*Tsuga heterophylla*) that can live for centuries. Note complex structures and layering from the ground-up.

Fig. 4 Primary forest Lamington National Park, Australia Photo: D. DellaSala.

Attribute	Primary Forest	Logged Forest
Patch size and distribution	Large, intact connected at water shed scale – low extirpations	Small and fragmented (roads) – insular with high high turn over/extirpation
Biodiversity	Generally high across taxa and levels	Uniformly low with losses across levels
Keystone processes	Intact trophic levels, carbon uptake/storage, hydrology, soils, nutrient cycling, pollination, fire	Highly altered dominated by edge effects (predation, severe fires)
Successional stages	All seral stages present	Type conversions – use of herbicides/pesticides
Biological legacies	Abundant	Rare
Invasive species	Low	High
Climate change adaptation potential	Resistance/resilience; may act as refugia	Vulnerable, cumulative impacts

If a Tree Falls Does Anybody Care (Status of the World's Forests)?

The deforestation footprint of humanity goes back thousands of years to at least the time when Vikings were sailing ships across the Atlantic and the Roman empire was prospering. Throughout this long history, entire countries were deforested for agricultural expansion; wood for heating, smelting, leather manufacturing; masts for ships; and other needs (Williams, 2006). Notably, deforestation has been linked to the collapse of early civilizations and is an indicator of imminent collapse of current ones (see Diamond, 2005). Over time, ~45% of the world's original forests were destroyed, mostly within the last 100 years, as industrial societies, population pressures, and consumption levels rose dramatically (<https://www.cbd.int/forest/about.shtml>).

Fig. 7 Remaining intact areas (green) boreal forest, Canada, based on 2013 imagery (with permission from Databasin.org). An intact forest landscape (IFL) is defined by Global Forest Watch Canada as >50,000 ha (see databasin.org for details) with no visible human disturbances. At this coarse scale, some IFLs may actually have undetectable logging and forest roads within them and thus this is likely an overestimate.

Fig. 8 The world's forests by climatic domain. Compliments of FAO (2010), Rome (<http://www.fao.org/forestry/fra/80298/en/>).

Fig. 9 Monarch butterfly overwintering grounds at El Rosario Monarch Butterfly Preserve, central Mexico. Photo: B. Hartl with permission.

Contemporary forest losses can be tracked using a number of estimators of forest gains/losses to illustrate some of the problems with deforestation and forest degradation metrics and to showcase particular “hot spots” where forest losses are serious regional and global problems.

Total Forest Area

Using [FAO \(2016\)](#) reporting, total forest area (all categories, natural and otherwise) declined by 3% from 1990 to 2015, 4.128 billion ha to 3.999 billion. It should be noted that FAO considers forest losses to include natural disturbance events (insects, disease, forest fires). While forest cover is reduced, this is not equivalent to losses from logging given that forests are resilient to natural disturbances that reset successional processes (an exception being unnatural fires in the tropics). The change rate (gains/losses) in forests reported by FAO also is not comprehensive and there are differences in data quality among reporting countries ([Keenan et al., 2015](#)). Aside from general categories (primary, natural, planted), FAO statistics do not include forest quality, ecological integrity, intactness, and other factors important to forest functions on local, regional, and global scales. By contrast, when more ecologically based definitions are used (e.g., forest defined as > 25% cover), a lower bound (relative to FAO) of total forest cover is 3.269 billion ha in 2000, declining to 3.168 billion ha by 2005 ([Hansen et al., 2010](#)). Although even these estimators have limitations given the coarse resolution of MODIS imagery, FAO estimates need to be calibrated with finer resolution mapping at the country and regional level to improve forest reporting metrics using more ecologically based definitions (see [Table 1](#)).

Natural Forest Area

Further breaking down the FAO totals for 1990–2015, natural forest area declined by 6% (twice the percentage of all forest cover) from 3.961 billion ha to 3.721 billion ha, while planted forest (including rubber plantations) expanded from 168 million to 278 million ha ([Keenan et al., 2015](#)). Alarming, tropical forests declined (2010–15) at an annual rate of 5.5 million ha; however, this was 58% of the rate in the 1990s ([Keenan et al., 2015](#)). Tropical forest losses (2010–15) were greatest in Brazil (984 K ha per year; K = thousand), followed by Paraguay (325 K), Argentina (297 K), Bolivia (289 K), and Peru (187 K) ([Keenan et al., 2015](#)). In Asia, net annual losses were greatest in Indonesia (684 K) and Myanmar (546 K). Africa, Nigeria (401 K), Tanzania (372 K), Zimbabwe (312K), and Democratic Republic of Congo (311K) each lost forests ([Keenan et al., 2015](#)).

In contrast, temperate forest expanded at an annual rate of 2.2 million and boreal and sub-tropical remained relatively constant ([Keenan et al., 2015](#)). Forest area expanded in Europe, North America, the Caribbean, East Asia, and Western-Central Asia, while it declined in Central and South America, South and Southeast Asia, and Africa ([Keenan et al., 2015](#)). China reported greatest forest expansion during this period (2010–15). These estimates do not distinguish loss of primary forests from gains in planted forests.

Importantly, primary forest account for only 36% of the global forest cover ([Mackey et al., 2014](#)), declining by 40 million ha from 2010 estimates ([Fig. 10](#)); although [FAO, 2016](#) reports recent increases in primary forests due to more countries reporting. Nevertheless, there is uncertainty in this estimator given not all countries report, difficulty in detecting certain logging activities (e.g., selective logging) and hard to detect (from satellites) roads under dense forest canopies.

Fig. 10 Primary forest losses and gains based on FAO 2010 (photo: D. DellaSala). Note: recent increases are due to more countries reporting.

New spatially explicit (“big data”) forest monitoring systems are becoming increasingly available for real-time global and regional projections. Examples include.

- Global Forest Watch time lapse deforestation operated by the World Resources Institute (<https://www.globalforestwatch.org/>; Fig. 11),
- Google Earth platforms of time lapse deforestation rates (<https://earthengine.google.com/timelapse/#v=44.85742,-123.70911,9.608,latLng&t=0.00>),
- Deforestation tracking of the Amazon by Mongabay.com (<https://data.mongabay.com/brazil.html#land>);
- Satellite tracking and deforestation visuals provided by National Geographic (<https://www.nationalgeographic.com/environment/global-warming/deforestation/>).

In sum, we are getting better at tracking deforestation but not at stopping it. Nevertheless, FAO deforestation/degradation estimates should be calibrated using these platforms wherever possible (although it is difficult to track degradation from selective logging using remote systems).

Notably, according to WWF (Taylor et al., 2015), 230 million ha are projected to be deforested by 2030 within 11 “deforestation fronts,” if no actions are taken (Fig. 12). All of these major losses are in tropical regions; however, losses to primary forest and intact forest landscapes are a serious global problem as noted.

What are the Drivers of Forest Loss?

The United Nations Programme REDD+ (Reducing Emissions for Forest Degradation and Deforestation: <http://www.un-redd.org/>), encourages countries to develop action plans that reduce forest losses via conservation incentives. The program was developed by the Parties to the United Nations Framework Convention on Climate Change (UNFCCC) to reduce forest losses, which account for 17% of the global carbon emissions, more than the entire transportation network and second only to energy (<https://www.unredd.net/about/what-is-redd-plus.html>).

Importantly, the main drivers of deforestation in tropical countries are commercial and subsistence agriculture, while drivers of forest degradation are timber extraction, fuelwood collection, charcoal production, unnatural fire (as in tropical rainforests) and livestock grazing (Hosonuma et al., 2012). Keenan et al. (2015) report that as countries develop overtime there is a switch (transition) from net forest loss to net forest gain. However, before the inflection point to forest gain is reached, primary forest losses are substantial. Thus, recent gains in forest cover (mainly from planting) come largely at the expense of primary and intact forest landscapes during transitional shifts.

Deforestation rates also have been coupled to high rates of poverty (Zwane, 2007), loss of traditional languages (<https://www.language-magazine.com/deforestation-linked-to-language-loss/>), subjugation of aboriginal cultures (<https://wikispaces.psu.edu/display/AnthSpace/How+Tropical+Deforestation+Affects+Cultural+Environment>) (Figs. 13 and 14), and degraded ecosystem

Fig. 12 Deforestation fronts based on projections to 2030 from Taylor et al. (2015). With permission of WWF—World Wide Fund for Nature (Formerly World Wildlife Fund), Gland, Switzerland (© Text and graphics: 2015 WWF All rights reserved, H. Miller).

Fig. 13 Satellite image (2004) showing plumes of smoke from ranchers burning primary forest remnants near the border of Kayapo indigenous land in Brazil. Zimmerman.

services like clean water and climate regulation (<https://news.mongabay.com/2007/02/amazon-deforestation-damaging-critical-ecosystem-services/>).

Can We Save the Forest in Time?

The hopeful answer is yes, if the political will, disincentives to log primary forests are in place (e.g., regulations, policy reforms), stepped up conservation measures are being employed (e.g., investments in rapid transitions, non-logging income to local

Fig. 14 Kayapo meeting in 2014 uniting to protect traditional lands from incursions by miners. Photo with permission from B. Zimmerman.

communities), and land-tenure issues are resolved (e.g., aboriginal rights). Here, are some conclusions and recommendations from chapter authors of *Forest Biomes*:

- Dudley (this volume) estimates that 13% to 20% of the world's forests are in some form of protection and this needs to increase dramatically to achieve representation (e.g., half of Earth's forests in some form of protection) and sustainability goals.
- Javar-Salas (this volume) evaluates different conservation management and protection scenarios for dry Hawai'i forests showing that the status quo scenario will not achieve representation or resilience objectives without stepped up conservation.
- Gomez-Diaz (this volume) discusses the urgent need for protecting large fragments of pine-oak and humid montane forest belts in biologically diverse regions of Central Veracruz, Mexico where < 3% is protected and the remaining natural areas are essential for maintaining plant diversity and ecosystem services.
- Frelich (this volume) provides three major recommendations for boreal forests: (1) follow all of the articles of the Paris Climate Agreement to reduce greenhouse gas emissions and limit the magnitude of global warming; (2) establish large nature reserves to keep tracts of boreal forests in a primeval state (e.g. as proposed by the boreal songbird initiative) and; (3) manage remaining areas outside reserves under enforced forest certification standards.
- Maser (this volume) recommends protecting intact forests so carbon can be captured from the atmosphere and cycled through forests in sufficient quantities.
- Houghton (this volume) indicates that without a massive, global program of forest expansion, the potential for negative emissions from ending deforestation and forest degradation is modest and small relative to fossil fuel reserves.
- Ibisch (this volume) calls on policy-makers to give roadless areas conservation priority in sustainable development.
- Abrams (this volume) argues that nations need to conserve biodiverse old world tropical rainforests to avoid collapse of well-known charismatic megafauna.
- Krasilnikov (this volume) discusses the importance of montane cloud forests, a unique and highly fragmented system endangered by climate change, agricultural expansion and intensive logging that should be protected in natural heritage sites.
- Kulakowski et al. (this volume) discuss how logging following insect outbreaks, windstorms, and fires amounts to a secondary disturbance that can inhibit ecosystem resilience.
- Curry and Cornelisse (this volume) review the ecological and social setting of overwintering forests used by iconic migratory monarch butterflies, an endangered migratory phenomenon.
- Kerr (this volume) proposes shifting most fiber production from forests to farmlands by 2040 to relieve pressure on forests.
- Hall (this volume) discusses how forestry practices can be improved through independent third-party certification that balances social, economic, and ecological factors.
- Zimmerman (this volume) discusses the importance of protecting aboriginal land tenure and cultural lifestyles in Amazonia, a region under enormous threats from illegal logging, ranching, and gold mining incursions on aboriginal territory.
- Roth (this volume) argues that the Klamath-Siskiyou bioregion of southwest Oregon/northern California will continue to act as refugia for native species provided substantial reversal of habitat loss, particularly old-growth forests.
- Niemi (this volume) explains the contributions forests make to human well-being by providing ecosystem services that generate benefits for individuals, families, businesses, communities, and the global society.
- Urquhart (this volume) discusses the amazing biodiversity of the largest expanse of rainforest on the planet in the Neotropics, and how deforestation primarily from agriculture is affecting regional climatic processes.

- Graham (this volume) highlights opportunities and challenges in reducing emissions from forests, and offers a regional perspective from Southeast Asia; a region in the spotlight for the mass expansion of oil palm plantations and frequently occurring wildfires.
- Furnish, in two articles (this volume), provides his personal accounts of how >23 million ha of national forest roadless area protections in the US was among the great conservation achievements in public land history, and how emergent forest restoration on Oregon's Siuslaw National Forest charted a path forward from old growth logging.
- Coxson et al. (this volume) describe the globally unique inland temperate rainforest and interior wetbelt of northwest North America, especially the extraordinary epiphytic lichen diversity and imperiled mountain caribou.
- DellaSala (this volume) discusses how plantations are "fake" forests in terms of greatly altered species composition, structure, and processes but that existing plantations may offset the need to log old-growth forests on the Tongass rainforest in southeast Alaska.

All told, there are unprecedented impacts to forests globally, accumulating in space and time as fewer intact landscapes and primary forests remain, more species are pushed to the brink of extinction, and natural forests are displaced by planted ones lacking biodiversity and ecosystem services. Many policies have been proposed to end deforestation and forest degradation globally as summarized.

The Paris Climate Agreement (Article 5) emphasizes the critical importance of forests in helping to stabilize climate change (Box 1).

The Convention on Biodiversity (<https://www.cbd.int/sp/targets/rationale/target-5/>) Target 5 states: "by 2020, the rate of loss of all natural habitats, including forests, is at least halved and where feasible brought close to zero, and degradation and fragmentation is significantly reduced (Box 2).

Box 1 Paris Climate Agreement with respect to forest carbon "sinks and reservoirs"

<https://climatefocus.com/sites/default/files/20151223%20Land%20Use%20and%20the%20Paris%20Agreement%20FIN.pdf>

Article 5 (1) Parties should take action to conserve and enhance, as appropriate, sinks and reservoirs of greenhouse gases as referred to in Article 4, paragraph 1(d), of the Convention, including forests. (2) Parties are encouraged to take action to implement and support, including through results based payments, the existing framework as set out in related guidance and decisions already agreed under the Convention for: policy approaches and positive incentives for activities relating to reducing emissions from deforestation and forest degradation, and the role of conservation, sustainable management of forests and enhancement of forest carbon stocks in developing countries; and alternative policy approaches, such as joint mitigation and adaptation approaches for the integral and sustainable management of forests, while reaffirming the importance of incentivizing, as appropriate, non-carbon benefits associated with such approaches.

Box 2 Convention on Biological Diversity (Conference of the Parties, United Nations).

Nearly all Parties report that habitat loss is the most important factor driving biodiversity loss. Largely undisturbed or *primary habitat* is a particular priority for reducing this loss (emphasis added). Degradation, which reduces the capacity of ecosystems to provide goods and services, is similarly important. Habitat fragmentation, though more difficult to quantify at a global level, is a related pressure driving biodiversity loss. While economic, demographic and social pressures are likely to mean continued habitat loss, degradation and fragmentation, particularly due to land use change beyond 2020, the rate of change needs to be substantially reduced. While for some ecosystems it may be possible to bring the rate of habitat loss close to zero by 2020, for others a more realistic goal is to halve the rate of loss. Significantly reducing habitat degradation and fragmentation will also be required in order to ensure that those habitats which remain are capable of supporting biodiversity. Ultimately, there must be limits to the conversion or degradation of natural habitats. This is particularly the case for some ecosystems, where continued loss risks passing "tipping points" that could lead to large scale negative effects on human well being. The target refers to rate of loss, and should be regarded as a step toward halting the loss of natural habitats. Further it should be noted that the use of net rather than gross rates of loss could obscure the loss of mature ecosystems as a result of restoration. Whilst restoration activities can restore many of the attributes of primary ecosystems, they cannot be restored completely in the short to medium term. The emphasis of this target should be on preventing the loss of high-biodiversity value habitats, such as primary forests and many wetlands. Recent evidence suggests that the global rate of deforestation is already decreasing.

Implementation: Reduction in the loss and degradation of natural habitats through land use change could be achieved through improvements in production efficiency and land use planning, and enhanced mechanisms for natural resource governance combined with recognition of the economic and social value of ecosystem services provided by natural habitats. In particular, catchment value (water provision), erosion control, the value of carbon sequestration by forests and wetlands, and other ecosystem services (such as denitrification by wetlands) provide contemporary incentives for reducing the net loss of these habitats, and reversing their decline. Taking a landscape-wide perspective to land use planning offers a useful way to integrate global level ecosystem services (e.g., climate change mitigation) with local level ones (e.g., biodiversity conservation, water supply and quality, timber and non-timber forest products). The programmes of work on forest, marine and coastal, inland water and dry and sub-humid lands biodiversity and the Convention's work on sustainable use are particularly relevant to this target. An initiative that could be further built upon in working toward this goal relates to the signing, by Ministers of 68 Parties to the Convention on Biological Diversity during the ninth meeting of the Conference of the Parties, of WWF's call to stop net deforestation by 2020.

Box 3 Example goals NY Forest Declaration.

Goal 1: At least halve the rate of loss of natural forests globally by 2020 and strive to end natural forest loss by 2030. Based on estimates provided by the signatory parties, relative to 2001–13, the average gross annual rate of global tree cover loss was 42% higher in 2014–17, the years following adoption of the resolution.

Goal 6: Include ambitions, forest conservation and restoration targets for 2030 in the post-2015 global development framework as part of new international sustainable development goals, providing a means for countries to integrate forest conservation into sustainability platforms.

The 2014 New York Forest Declaration (**Box 3**), endorsed by > 190 governments, corporations, nongovernmental and indigenous peoples' organizations, included ten ambitious goals aimed at halting natural forest loss by 2030 (<http://forestdeclaration.org>).

The Secretariat of the Convention on Biological Diversity (CBD Secretariat) in 2014 adopted 20 global targets under the strategic plan for biodiversity 2011–20. The targets were grouped by five strategic goals:

1. Address the underlying causes of biodiversity loss by mainstreaming biodiversity across government and society.
2. Reduce the direct pressures on biodiversity and promote sustainable use.
3. Improve the status of biodiversity by safeguarding ecosystems, species and genetic diversity.
4. Enhance the benefits to all from biodiversity and ecosystem services.
5. Enhance implementation through participatory planning, knowledge management and capacity building.

A vision for forests in a sustainable world—global conservation initiatives need to be advanced alongside sustainable development if we are going to save the world's forests in time (e.g., see <https://sustainabledevelopment.un.org/?menu=1300>). Sustainability strategies need to stop and then reverse the loss of natural forests through restoration and protection of primary forests and intact forest landscapes because they are irreplaceable in human lifetimes. Ecologically meaningful increases in forest protections (at least half of a given region in some form of protection, see Noss et al., 2012; <https://www.half-earthproject.org/>), responsible forest management (e.g., FSC), and reduced/shifted consumption of wood fiber (e.g., alternative fibers, fallowed agricultural lands) are critical to a sustainable relationship with forests and any hope for a wild planet where forest creatures of all shapes and sizes prosper, the climate is safe, clean drinking water is available (**Fig. 15**), especially to the economically disadvantaged, and the cultural connections and survival of aboriginal peoples are passed on from generation to generation. Importantly, proforestation—growing and restoring existing forests to become intact overtime—needs to be implemented to maximize carbon sequestration, biodiversity, water and air quality, flood and erosion control, public health, recreation, and scenic beauty (Moomaw et al., 2019). The alternative, widespread deforestation and forest degradation, will forever compromise the irreplaceable services we receive from the world's forests.

Abstract

Beginning with the investment of solar energy and the reinvestment of carbon dioxide, water, and minerals from the soil, every forest is a source of sequestered carbon through photosynthesis, which is then stored and recycled worldwide. Within each forest, various mammals and birds eat mycorrhizal fungi that help connect the flow of energy from trees' crowns to their roots, and from their roots to their crowns. As trees grow, they sequester and store carbon. As they die and fall to the forest floor, they not only created a micro-topography that conserves water and helps prevents soil from creeping downslope but also reinvest their stored carbon and other elements in the soil, thereby nurturing the next forest. And, some of the fallen trees make their way, as driftwood, into the oceans, where they help balance the marine-carbon requirements that sustain oceanic life worldwide.

All things in Nature's forest are neutral. Nature assigns no values. Each piece of a forest, whether a bacterium or a 1000-year-old tree, is allowed to offer its evolved structure, carry out its evolved function, and interact with other components through their evolved, interrelated processes. None is more valuable than another; each is only different from the countless others. However, assigning a value to something in the forest—like a tree as a commercial product—begins to adjust that object in our focus, where bringing one thing into focus simultaneously forces almost everything else out of focus. For example, rodents were poisoned for decades in the name of forestry, because they were perceived as having only a negative value. They ate the seeds that industry wanted to grow into merchantable trees. Today, forest rodents are viewed differently. Some still eat tree seeds, but at the same time they disperse viable spores of mycorrhizal fungi, nitrogen-fixing bacteria, and yeast, which, working in unison, stimulate tree growth and thus the acquisition and storage of carbon in a forest.

How Carbon Gets Into and Moves Around in a Forest

The following vignette of the northern flying squirrel in the coniferous forests of the Pacific Northwestern United States illustrates but one example of the myriad dynamic, interdependent relationships in forests the world over, beginning with solar energy.

The Only True Investment in a Forest

The *only true investment* in a forest is energy from solar radiation (materialized sunlight), which takes an average of 8 min and 20 s to reach the Earth and affects all life worldwide in one way or another (Cain, 2018). Everything else is merely the recycling—reinvestment—of already-existing energy.

In a business sense, for example, one makes money ("economic capital") and then takes a percentage of those earnings and *recycles* them by putting them back into the infrastructure of the enterprise for maintenance of buildings and equipment to facilitate making a profit by protecting the integrity of the initial outlay of capital over time. In a business, one recycles economic capital *after* the profits have been earned.

However, the “biophysical capital,” of a forest must be “recycled” *before* the profits are earned, if the forest is to remain biophysically sustainable. This means forgoing some potential monetary gain by leaving enough of a forest ecosystem intact for it to function in a productively sustainable manner. For instance, one must leave some proportion of the merchantable live trees to gather enough solar radiation and produce living tissue, wherein carbon is sequestered, that will subsequently die—and together with the already-dead trees—rot, recycle into the soil, and thereby replenish the fabric of the living system. With this in mind, and because I am writing about a forest (a highly complex, biophysical system), I will focus my discussion primarily on the trees, wherein the sequestered carbon is temporarily stored.

It has long been understood that green plants use chlorophyll molecules to absorb sunlight and use its energy to synthesize carbohydrates from carbon dioxide and water. These carbohydrates, in turn, are partly stored energy from the sun (an original input) combined with carbon dioxide and water, as well as nutrients from the soil in which the trees grow (all existing—recycled—chemicals), to create a renewable source of energy (Cheng and Fleming, 2009; May, 2018). This process is known as “photosynthesis,” from the Greek *photo* (“light”), *syn* (“with, together”), and *thesis* (“putting, placing”). In other words, photosynthesis is the fusion of energy embodied in sunlight with the recycled energy stored in earthly materials.

The Fungal Connection

The combination is the basis for sustaining the life processes of plants in every forest because a tree’s leaves or needles capture sunlight, transform it into carbohydrates, which travel from a tree’s crown, through the trunk into the roots, where an obligatory, symbiotic relationship is formed with certain fungi central to the processes of the tree’s capturing nutrients from the soil. In fact, fossil evidence of the earliest terrestrial plants, as well as current molecular studies, show that plant roots and certain fungi coevolved as symbiotic partners to form structures known as *mycorrhizae*, a word that comes from the Greek *mykes* (a fungus) and *rhiza* (a root). Mycorrhizae are generally distributed throughout forests worldwide (Maser et al., 2008; Calvo et al., 1989).

The hyphae, or individual fungal strands, each one to two cells thick, form the main structural elements of the mycorrhizal fungi. (“Hypha,” singular, comes from the Greek *hyphe*, a web.) The hyphae either penetrate the cells of a plant’s roots to form an “endomycorrhiza” (*endo* = mycorrhiza *inside* the root) or ensheath the root of form an “ectomycorrhizae” (*ecto* = mycorrhiza *outside* the root).

In the nutrient-deficient conditions of most forests, at least 90% of a tree’s “feeding” roots are colonized by ectomycorrhizal fungi and results in a layer of fungal tissue or “mantle” that forms around the tree’s roots (Photo 1), thereby creating an active, reciprocity of life, with the tree as the conduit, between the investment of solar energy and the inorganic, soil elements. From this mantle, individual hypha aggregate and organize into root-like structures called “rhizomorphs” (*rhizo* = root + the Greek *morphe* = shape) that grow out from the feeding roots into the soil, where they act as an extension of the tree’s root system. The aggregate of hyphae is also referred to as “mycelia” (singular = mycelium), which in New Latin means “made of mushrooms.” A mycelium is a given mass of hyphae that forms the nonreproductive part of a fungus.

Some mycorrhizal fungi are host-specific, meaning that a given mycorrhizal fungus colonizes a single species of plant, whereas others are generalists and colonize a number of host plants. Douglas-fir (*Pseudotsuga menziesii*) or birch (*Betula* spp.), for example, can be colonized by many species of mycorrhizal fungi. In turn, these fungi extend from tree to tree and so form linkages among trees. The generalized nature of host compatibility ensures that almost all trees, and many other plants, in an undisturbed forest ecosystem, regardless of species, are interconnected by billions of miles (kilometers) of hyphae, organized into mycelial systems, that stem from a diverse population of mycorrhizal fungi. If, therefore, you could pull up a whole forest and gently wash the soil from the roots of the plants, you would find a mycelial net connecting the entire forest—one of the reasons an old-growth forest is so retentive of its soil-nutrient capital (Read, 1997, 1998; van der Heijden et al., 1998).

Ectomycorrhizal fungi profoundly affect the forest ecosystem. Through the obligatory, symbiotic mycorrhizal association, a plant, such as Douglas-fir, provides carbohydrates to its mycorrhizal symbiont, while the fungal symbiont mediates the plant’s uptake of nitrogen, phosphorus, other minerals, and water. In addition, the mycorrhizal association promotes the development of fine roots; produces antibiotics, hormones, and vitamins useful to the host plant; protects the plant’s roots from pathogens and environmental extremes; moderates the effects of heavy metal toxins; and promotes and maintains soil structure and the forest food web. This mycorrhizal association is expensive, however, with an estimated 50%–70% of the host plant’s net annual productivity being translocated through the roots of the plant to their associated mycorrhizal fungi (Amaranthus et al., 1966; Luoma, 2001; Smith et al., 2002).

When access to nutrients is increasingly restricted in a forest ecosystem that is already nutrient-impovertished, mycorrhizal fungi can influence both the interactions among plants and the species composition of the plant community itself. It appears there is an additive, beneficial effect that comes with each species of mycorrhizal fungus that colonizes a given plant, which, in turn, could mean that both biodiversity and ecosystem productivity, as well as the acquisition and storage of carbon, will increase with an increasing number of fungal symbionts. This scenario seems likely because experimentation has shown that, as the number of fungal symbionts is increased, so too is the collective biomass of roots and shoots, as well as the species diversity of the plant community. Conversely, as a forest is disturbed through exploitive forestry practices and the use of artificial fertilizers, the function of the mycorrhizal system can be impaired.

In addition to gleaning nutrients from the soil and translocating them into the host plant, mycorrhizal fungi, along with roots of the host plant and the free-living microbial decomposers in the soil, are significant components of the global balance of carbon. Much of the carbon balance is mediated by photosynthesis and drives the respiration or “breathing” of the soil. Both photosynthesis

Photo 1 Note the light-colored tissue of an ectomycorrhizal fungus forming a “mantle” around the lodgepole pine’s (*Pinus contorta*) root tips. USDA Forest Service Photograph by C.P.P. Reid.

and mycorrhizal symbionts are critical in maintaining the soil’s respiration, through which carbon is extracted from the soil. Although the carbon made available to the soil through photosynthesis helps to balance the loss of carbon from the soil through respiration, the production of photosynthates is mediated more by annual seasonality than by the temperature of the soil (Högberg et al., 2001).

The Truffle Connection

Truffles—the belowground, fungal fruiting-bodies—are the initial link between, mycorrhizal fungi, and the northern flying squirrel (*Glaucomys sabrinus*). Flying squirrels nest and reproduce in the tree canopy and come to the ground at night where they dig and eat truffles. As a truffle matures, it produces an aroma that attracts the foraging squirrel. Evidence of a squirrel’s foraging remains as shallow pits in the forest soil and, occasional, partially eaten fruiting-bodies (Pyare and Longland, 2001).

Truffles contain the nutrients required by the small animals that eat them. In addition to nutritional value, truffles also contain water, fungal spores, nitrogen-fixing bacteria, and yeast, all of which become important in the forest network.

The Squirrel Connection

Keeping the above in mind, let’s consider the coniferous forests of the Pacific Northwest in which Douglas-fir and western hemlock (*Tsuga heterophylla*) predominate in the old-growth canopy. Herein live the Northern Spotted Owl (*Strix occidentalis*), which preys on the flying squirrel as a staple of its diet (Forsman et al., 1984; Thomas et al., 1990; Carey, et al., 1990; Maser, 1998). The flying squirrel, in turn, depends on truffles, which it digs out of the forest soil.

When flying squirrels eat the truffles, they consume fungal tissue that contains nutrients, water, viable fungal spores, nitrogen-fixing bacteria, and yeast (Photo 2). Pieces of truffle move to the stomach, where the tissue is digested; then on through the small intestine, where absorption takes place, and then to the cecum. The cecum is like an eddy along a swift stream; it concentrates, mixes, and retains fungal spores, nitrogen-fixing bacteria, and yeast. Undigested material, including cecal contents, is formed into excretory

Photo 2 A truffle. USDA Forest Service Photograph by James M. Trappe.

pellets in the lower colon; these pellets, which are expelled through the rectum, contain the viable spores and accompanying microorganisms necessary to inoculate the root tips of trees.

The Pellet Connection

Flying squirrels dine heavily on truffles. The fate of their fecal pellets varies, however, depending on where they fall. In the forest canopy, the pellets might remain and disintegrate in the tops of the trees. Or a pellet could drop to a fallen, rotting tree and inoculate the wood. On the ground, a squirrel might defecate on a disturbed area of the forest floor, where a pellet could land near a feeder rootlet of a Douglas-fir that may become inoculated with the mycorrhizal fungus when the spores, having been washed into the soil by rain, germinate. If environmental conditions are suitable and root tips are available for colonization, a new fungal colony may be established. Otherwise, hyphae of germinated spores may fuse with an existing fungal thallus (the nonreproductive part of the fungus) and thereby contribute and share new genetic material (Maser et al., 1978a,b, 1985, 1986; Luoma, et al., 2002).

A fecal pellet is more than a package of waste products; it is a “pill of symbiosis” dispensed throughout the forest. Flying-squirrel pellets usually contain four components important to the forest: (1) viable spores of mycorrhizal fungi, (2) yeasts, (3) nitrogen-fixing bacteria, and (4) the complement of nutrients necessary for the survival and function of the nitrogen-fixing bacteria—like the yolk that feeds the chicken forming in the white of an egg.

The yeast, as a part of the nutrient base, has the ability to stimulate both growth and nitrogen fixation in the bacterium *Azospirillum* spp. Nitrogen thus made available can be used both by the fungus and the host tree. Yeast cells may also aid spore germination because spores of some mycorrhizal-forming fungi are stimulated in germination by extractives from other fungi, such as yeasts (Li and Castellano, 1995; Li et al., 1986a,b; Li and Maser, 1986).

The northern flying squirrel thus exerts a dynamic, functionally diverse influence within the forest. The complexity of effects ranges from the crown of the tree inhabited by the squirrel, from which it can rain fecal pellets to the soil, where the fungi depend on large, rotting trees lying on and buried in the forest floor for water and the formation of humus. *Humus*, which lends soil its dark color, is the Latin word for “the ground, soil” or alternatively the New Latin word *humos*, meaning “full of earth.” Further, nitrogen-fixing bacteria occur on and in the ectomycorrhizae, where they convert atmospheric nitrogen into a form that is usable by both fungus and tree (Li et al., 1986a,b).

The pellets contain spores, microorganisms, and nutrients, which work into the soil’s root zone, where the fungi form mycorrhizae that absorb nutrients, which are conducted into the roots, up the trunk, and into to the crown of the tree, perhaps into the squirrel’s own nest tree. The trees, in turn, help to create the forest, which may be part of a catchment basin that collects and stores water required for human consumption—drinking, irrigation, or electricity, which says nothing of wood products, foods, and medicines used as products to sustain the material comfort of society—all thanks to the help of forest-dwelling rodents and fungi, which touch the quality of our lives in so many ways. The consequence of the foregoing is that trees sequester carbon as they grow, carbon that is not only stored but also helps to shape the forest.

The Rotting Wood Connection

To add to the overall complexity of a late-successional, indigenous forest, a live old tree eventually becomes injured and/or sickened with disease and begins to die. How a tree dies determines how it decomposes and reinvests its biophysical capital (organic material, carbon, and other chemical elements) into the soil and eventually into the next forest.

A tree may die standing as a snag to crumble and fall piecemeal to the forest floor over decades, or it may fall directly to the forest floor as a whole tree. How a tree dies, is important to the productive sustainability of the forest because its manner of death determines the structural dynamics of its body, as habitat. Structural dynamics, in turn, determine the biological-chemical diversity hidden within the tree's decomposing body, as ecological processes incorporate the old tree into the soil from which the next forest must grow. What goes on inside the decomposing body of a dying or dead tree is one example of the hidden biological and functional diversity that is totally ignored in a typical economic valuation of a forest. Consequently, that trees continue to become injured, diseased, and die is critical to the long-term biophysical sustainability of a forest that itself is an interactive, organic whole defined not by the pieces of its body, but rather by the interdependent functional relationships of those pieces creating the whole—the intrinsic value of each piece and its complementary function.

Regardless of how it dies, the snag or fallen tree is only an altered state of the live tree; so, the large, live tree must exist before there can be a large snag or large fallen tree. A basic problem inherent in understanding this scenario lies in the fact that, if asked, few of the world's leading scientists, legislators, policy-makers, or business executives could name the five classical Kingdoms of Nature (bacteria, fungi, algae, plants, and animals) or explain how they complement one another. This dearth of ecological literacy shows a basic lack of understanding how ecosystems—and their self-reinforcing, biophysical, feedback loops—work, as well as a basic lack of understanding the long-term, systematic consequences of short-term, symptomatic, political/economic decisions.

Finally, the various functions of individual species, when melded in the collective, form a self-reinforcing feedback loop of mutually dependent interrelationships in which the spotted owl preys on the flying squirrel; the flying squirrel eats the truffle; the fungus is closely associated with large wood on and in the forest floor for water and the formation of humus (the fungus, spotted owl, and flying squirrel are all dependent, either directly or indirectly, on the same large, decomposing wood on the forest floor). The fungus feeds the tree; the tree feeds the fungus; the squirrel inoculates the trees roots with fungal spores that help keep the tree alive and growing. The tree houses the flying squirrel and the spotted owl, and so on (Maser and Trappe, 1984; Maser et al., 1979, 1984a,b).

How Carbon Stored in Trees Shapes a Forest

How a tree dies is important to the health of the forest because its manner of death determines the structural dynamics of its "body" as habitat. A tree may die standing as a snag to crumble and fall piecemeal to the forest floor over decades. Or, it may fall directly to the forest floor as a whole tree. To reiterate, regardless of how it dies, the snag and the fallen tree are only altered states of the live tree. Consequently, the live old-growth tree must exist before there can be a large snag or a large fallen tree.

There are three major sources of coarse woody debris in an old-growth Douglas-fir forest: (1) uprooting of live trees, with or without complete crowns; (2) breakage of crown and stem of live trees; and (3) breakup and fall of snags. Because size of trees and the manner in which woody material comes to be on the ground varies widely, the resulting pieces of woody debris are heterogeneous in size and shape. Regardless of its original size, wood passes through the various stages of decay; the smaller it is, the faster it breaks down and disappears.

Structural dynamics of a dying or dead tree, in turn, determine the biological/chemical diversity hidden within the tree's decomposing body, greatly affecting the ecological processes that incorporate the old tree, and its stored carbon, into the soil from which the next forest must grow. What goes on inside the decomposing body of a dying or dead tree is the hidden biological and functional diversity that is totally ignored by economic valuation. Consequently, the fact that trees become injured and diseased, die, and remain in place is critical to the long-term structural and functional sustainability of a forest. The forest is an interactive, organic whole defined, not by the pieces of its body, but rather by the interdependent, functional relationships of those pieces—the intrinsic value of each piece and its complementary function as they interact to create the whole.

Placement of Fallen Trees

Fallen trees that are oriented horizontally along the contours of a slope seem to be used more by vertebrates than are trees vertically oriented across contours, especially on steep slopes. Large, stable trees lying along contours help reduce erosion by forming a barrier to creeping and raveling soils. Soil and nutrients deposited along the upslope side of fallen trees reduce loss of nutrients from the site. Such spots are excellent for the establishment and growth of vegetation, including tree seedlings.

Vegetation becomes established on and helps stabilize this new soil, and, as invertebrates and small vertebrates begin to burrow into the new soil, they not only nutritionally enrich it with their feces and urine but also constantly mix it by their burrowing activities.

The interactions of fallen trees with soil are directly affected by steepness of slope and ruggedness of terrain; a fallen tree on flat ground, for example, is much more likely to contact the soil over its entire length than is one oriented either across or along contours on steep or rough terrain (Photo 3). The proportion of a tree in contact with the soil affects the water-holding capacity of the wood. The moisture retention in fallen trees in old-growth Douglas-fir forests through the summer drought is best in the side of trees in contact with the soil. The moisture-holding capacity of the wood, in turn, affects its internal processes and therefore the succession of plants and animals. In addition, the orientation of a fallen tree to aspect and compass direction and the amount and duration of sunlight it receives, drastically affect its internal processes and biotic community.

Photo 3 A fallen tree lying across another. Note that the one underneath is in direct contact with the forest floor. Photograph by Chris Maser.

How Fallen Trees Are Reinvested in the Forest Soil

A newly fallen tree interacts only passively with the surrounding forest because its interior is not accessible to plants and most animals. But once fungi and bacteria, which are smaller than the wood fibers, gain entrance, they slowly dissolve and enter the wood cells, and wood-boring beetles (Coleoptera), carpenter ants (*Camponotus* spp.), and termites (Isoptera) chew their way through the wood fibers. Meanwhile, many other organisms, such as plant roots, mites (Acari), springtails (Collembola), amphibians, and small mammals, must await the creation of internal spaces before they can enter. The flow of plant and animal populations and communities, air, water, and nutrients between a fallen tree and its surroundings increases as the tree's decomposition process continues. For example, the water-holding capacity of a large, fallen tree varies by day, season, year, decade, and century, adding yet another dimension of diversity to the forest.

Surface area develops within a fallen tree through physical and biological processes. A tree cracks and splits when it falls and then dries. Microbial decomposition breaks down the cell walls and further weakens the wood. Wood-boring beetle larvae and termites tunnel through the bark and wood, not only inoculating the wood with microbes but also opening the tree to colonization by other microbes and small invertebrates. Wood-rotting fungi produce zones of weakness, especially between the tree's annual growth rings, by causing the woody tissue laid down in spring to decay faster than that laid down in summer. Plant roots that penetrate the decayed wood split and compress it as the roots elongate and thicken in diameter. Because of all this internal activity, the longer a fallen tree rests on the forest floor, the greater the development of its internal surface area. Most internal surface area results from biological activity, the cumulative effects of which not only increase through time but also act synergistically—insect activity promotes decomposition through microbial activity that encourages the establishment of rooting plants.

Thus, fallen trees offer myriad organisms multitudes of external and internal habitats that change yet persist through the decades. Of the organisms, only the casual observer might notice a few of the fungi, such as mushrooms or bracket fungi. These structures, however, are merely the fruiting bodies produced by mold colonies that run for miles (kilometers) within the tree. Many fungi fruit within the fallen tree; so, they are seen only when the tree is torn apart. Even then, only a fraction of the fungi present might be noticed because the fruiting bodies of most appear for only a short time. The smaller organisms, not visible to the unaided eye, are also important components of the forest. We humans do not begin to grasp the notion that microbes and fungi change a forest just as surely as a raging fire, only inconspicuously and more slowly. There is an unseen function that is just as critical, and just as great as any in the forest. We are awed by a towering fir but not by a lowly fungus, and yet it is the fungi that convert the tree to soil and eventually to a new forest with its sequestration and storage of carbon (Maser and Trappe, 1984; Maser, 1989).

Therefore, it is not only species of plants and animals that become extinct with the liquidation of a late-successional forest but also the old "grandparent trees." As crop after crop of young trees replace liquidated old trees, the ecological functions performed by the old trees, such as creation of the "pit-and-mound" topography on the floor of the forest with its mixing of mineral soil and organic topsoil, become extinct processes. Why? Because there are no more grandparent trees to blow over; yet, "windthrow," which creates "blowdown," is an extremely important event in forests, especially in such forests as those in southeast Alaska, where fire plays a minimal role in the disturbance regime, but windthrow is critical (Bormann et al., 1995; McClellan et al., 1990; Deal et al., 1991).

Pit-and-Mound Topography

“Pit” refers to the hole left in the forest floor, as a tree’s roots are pulled from the soil, and “mound” refers to the soil-laden mass of roots, called a “rootwad” suddenly thrust into the air above the forest floor as the old tree topples. The young trees that replace the grandparent trees are much smaller and different in structure; so, they cannot perform the same functions in the same ways. Of all the factors that affect the soil of the forest, the roughness of the surface caused by falling grandparent trees, particularly the pit-and-mound topography, is the most striking.

Uprooted trees enrich the forest’s micro-topography by creating new habitats for vegetation. They also provide opportunities for new plants to become established in the bare mineral soil of the pit and the mound. In addition, fallen trees open the canopy, allowing additional light to reach the floor of the forest, that, in combination with the pits and mounds, creates and maintains a richness in the species of plants forming the understory and the herbaceous ground cover. As large trees fall, they bring with them nitrogen-rich lichens from the canopy to the forest floor, where the lichens decompose and add their nitrogen to the soil layer. With time, the fallen tree itself presents habitats that can be readily colonized by tree seedlings and other plants.

Extinction of the grandparent trees changes the entire complexion of the forest through time, just as the function of a chair is changed when the seat is removed (Photo 4). The “roughness” of the forest floor that, over the centuries, resulted from the

Photo 4 A “grandparent” Sitka spruce along the Oregon coast surrounded by young trees. Photograph by Chris Maser.

cumulative addition of pits, mounds, and fallen grandparent trees will become unprecedentedly “smooth”—without pits and mounds; without large, fallen trees.

Water moves differently over and through the soil of a smooth forest floor, one that is devoid of large, fallen, rotting trees acting as reservoirs, storing water throughout the heat of summer, and holding soil in place on steep slopes. Gone are the huge snags and fallen trees that acted as habitats for creatures wild and free. Gone are the stumps of the grandparent trees with their belowground “plumbing systems” of roots hollowed out by rot that guided rain and melting snow deep into the soil (Photo 5).

This plumbing system of decomposing tree stumps and their large, deep, hollow roots frequently form interconnected, surface-to-bedrock channels that rapidly drain water from heavy rains and melting snow. As roots slowly rot away, the collapse and plugging of these channels forces more water to drain through the soil matrix, reducing its cohesion and increasing the hydraulic pressure, thereby increasing the probability of mass soil movements.

These plumbing systems cannot be replaced by the young trees of modern forests because their roots are too small and shallow to form the conduits necessary to rapidly move large quantities of water deep into the soil. Local extinctions of the ecological functions performed by grandparent trees, alive and dead, seems to pass unnoticed into the shadow-realm of bygone forests because their passing takes place unnoticed in the “invisible present.”

And, finally, the world’s forests send a percentage of their stored carbon, in for form of driftwood, to the oceans of the world, where its structure and function is critical to the biophysical integrity and productive sustainability oceans worldwide.

How Carbon Leaves a Forest and Feeds the Ocean

Leaving the rivers of the world, driftwood enters the oceans, where the currents transport it throughout the worldwide seascape. For example, driftwood along the shores of Iceland takes 4–5 years, traveling between 250 and 620 miles (402 and 998 km) each year, to reach Iceland from the North coast of Siberia ([An International Team of Scientists Studying Driftwood Along Icelandic Shores, 2016](#)).

Driftwood in the Open Ocean

Trees drifting at sea are usually heavily populated with plants and animals, including both pelagic and nearshore species, acquired during the tree’s transit to the open ocean. Once in the open ocean, other organisms use them.

In addition to the organisms actually attached to or secreted within the driftwood itself, communities or other organisms form around it. More than a 100 species of invertebrates and some 130 species of fishes are known to congregate on and around floating objects. With respect to these open-ocean communities, wind-induced water movements in the ocean’s upper layer are among the most important factors leading to the aggregation and survival of organisms near driftwood.

The formation of communities associated with driftwood, particularly fishes, may depend on shade, refuge from predaceous fishes, an abundance of food, or protection from waves. On the other hand, shadows cast by floating trees may make zooplankton more visible to predators or pelagic fishes simply seek shade. Then again, drifting trees may serve as sites for egg attachment, or where pelagic fishes can secure algal and invertebrate food, or where they can clean external parasites off themselves.

In addition, it’s thought that small fishes are initially attracted to a floating tree as a point of reference, swimming with it while feeding on the small planktonic organisms in its vicinity. Along with the planktivores come juveniles of carnivorous species and

Photo 5 The root of a mountain hemlock (*Tsuga mertensiana*) that has been hollowed out by rot and acts as a conduit for water to penetrate from the surface of the soil deep within the soil. Photograph by Chris Maser.

then, larger obligate predators arrive and eat the accumulated prey. Thus, within 3–5 weeks after a tree initially arrives in the open ocean, the combined weight of its associated tunas (*Thunnus* spp.) alone may reach as much as hundred tons.

The prey responds by using the floating tree as protection. The predators rapidly deplete the available prey, albeit only temporarily. In their search for food, the predators move away from the tree only to return and use it as a point of reference.

Large driftwood in general plays an important role in the life cycles of many eastern Pacific species by aggregating them, which would otherwise be dispersed throughout the pelagic environment, aggregations similar to those around islands and seamounts.

In fact, massive accumulations of large driftwood behaves essentially as free-floating islands or reefs. The ecological role played by these “free-floating islands” is probably different for different species because the assemblage is dynamic, changing in space and time, albeit with some degree of organization. The faunal aggregation may show different developmental stages, say changes in species composition, as the driftwood, entrained in the current, covers hundreds of miles (kilometers) through the weeks and months at sea.

It thus seems that driftwood is adaptive for most species in that some may seek shelter or food, but for most, driftwood is a vehicle bringing them into rich feeding grounds because driftwood, originating at river mouths, travels through biologically rich coastal areas and tends to accumulate in rich parts of the ocean. In this way driftwood can be used as “stepping stones” in the movements of large fishes, as it links major features in the circulation of ocean currents and the fishes’ migration paths with the location of a region’s islands and seamounts.

In the biogeographic sense, driftwood acts as free-floating islands, carrying subsets of epipelagic fauna from one biologically-rich area to another, an idea that can provide a unified approach to the ecological study of pelagic faunal assemblages associated with large driftwood in the open oceans of the world (Maser et al., 1988; Maser and Sedell, 1994; Maser, 2014).

Driftwood as Habitat and Food on the Ocean Floor

Although the sources, forms, and routes that supply organic material to the energy-poor deep sea are little known, it is known that drifting trees in nearshore currents become water-logged and sink over the continental shelves or in the deep sea, where they represent terrestrially-fixed carbon. In the Pacific Northwest and other areas, deep-sea, wood-boring bivalves (Mollusca) live in waters ranging from about 6000–11,500 ft (19,685–37,739 m) deep, where they rely on sunken driftwood for food.

There are at least three species of deep-sea wood-borers that quickly invade wood and grow rapidly, which, at a depth of about 6000 ft (19,685 m) in the North Atlantic, means wood can become infested with a dense population within 104 days. There, they convert wood into fecal pellets, which settle to the sediment surface and attract other bottom-dwelling animals. The conversion of wood into a readily available source of detritus supports the development of a complex, local community of bottom-dwelling organisms.

Deep-sea wood-borers have a high reproductive rate, grow rapidly, mature early, and have high-density populations, all of which are characteristics suitable for effectively using wood, the supply of which is erratic, unpredictable, and transient in the deep ocean. Their piles of fecal pellets, which are finely ground wood fragments, may attract more than 40 species of other deep-sea invertebrates. Enrichment of the bottom, a result of disintegrating wood and the accumulating fecal pellets, thus contributes to the development of a diverse fauna.

Wood in the deep-sea supplies energy in an energy-scarce environment and is a source of habitat diversity. It is not surprising, therefore, that a single, water-logged tree on the deep-ocean floor is the focus of intense and abundant life. Although wood is frequently found in dredges from fishing the deep-sea floor and deep-sea trenches, it is most common off mouths of rivers and wooded coastlines.

The complete role of intact driftwood in the open-ocean food web, whether it’s floating on the surface or resting on the bottom, remains unknown, as does the potential role of offshore, marine wood-borers in the initial reduction of wood. Nevertheless, 95% of the organic carbon from plant materials in the sediments off the mouth of the Columbia River, along the Northwest Coast of the United States, is terrestrial in origin. Organic carbon in the nearshore sand is about 20%, and that of midshelf silts, about 25 miles (40 km) offshore, is between 40% and 60%.

Although it takes years for large driftwood from the forest to finally reach the sea, the story cannot be told in the concept of time because it’s too limiting for an understanding of the myriad cycling pathways to which driftwood is subjected on its seaward journey (Maser et al., 1988; Maser and Sedell, 1994; Maser, 2014).

How and Why People Overexploit the Carbon in a Forest

When unconscious of something’s material value, we are free of its psychological grip. Yet, the instant we perceive its material value (“conversion potential” of trees into products), we also perceive the psychological pain of its potential loss, a fear that fosters the over-exploitation of our inherited natural resources, such as forests, because not to exploit them is perceived as losing the opportunity, as well as the coveted material value, to someone else. And it is this feeling of loss that we humans fight so hard to avoid. In this sense, it is more appropriate to think of resources “managing” us as opposed to us managing resources, which answers why the timber industry is so dogmatically insistent on cutting every old-growth tree. The industry has nothing invested in the growing of the old trees, and so ever old tree represents a “windfall profit.” The industry’s only investment is associated with getting the old trees—and thus the forest’s stored carbon—to the mill. In this sense, the timber industry knows exactly what it wants—old-

growth trees. How many it wants—all of them. When it wants them—now. Why it wants them—because they're essentially free for the taking. Where it wants them—at the mill. The profit margin is all that matters; so, the future is discounted. Karl F. Wenger, President of the Society of American Foresters, makes this point clear:

The fact is, Nature knows nothing. Nature is deaf, dumb, blind, and unconscious. . . . It reacts blindly and unconsciously according to the properties and characteristics of its components. These have no intrinsic values, since only the human race can assign values. Nature doesn't care what we do to it. . . . Clearly, the people's needs are satisfied much more abundantly by managed than by unmanaged forests.

(Wenger, 1998)

This said, the level of consciousness that created a problem in the first place is not the level of consciousness that can fix it. We must, therefore, raise our level of consciousness with respect to how we opt to caretake forests worldwide. We can do this because we, as a people, as a society, are *not* "locked" into our way of thinking. Because we, as a people, as a society, can always choose to choose again, there is hope for the generations of the future (Maser, 2004).

How Caretaking Allows Carbon to Maintain a Sustainable Forest

If we honor Nature, we can find the place where culture and Nature meet and both are more nearly sustainable, but that requires a reassessment of "waste." The economic concept of "waste" says in effect that anything not used directly by humans is wasted. But, in a biophysical sense, there is no such thing as waste in a forest or any other ecosystem—managed or unmanaged. Consider that a tree rotting in a forest, composting as it were, is a reinvestment of Nature's biophysical capital in the long-term maintenance of soil productivity, and hence of the forest itself. Biophysical capital includes such things as inorganic components, organic material, and biological and genetic diversity. And to reinvest means to invest again, to put back. How might this work? First, we must ask ourselves what we want from an acre of land, such as a forest, and then we must ask ourselves how we need to treat that acre to *allow* Nature to provide our desired outcome on a sustainable basis.

For example, an indigenous, old-growth forest has three prominent characteristics: large live trees, large standing dead trees or snags, and large fallen trees—none of which would exist without the biophysical system cycling carbon throughout the forest over the decades and millennia. As noted earlier, the large snags and the large fallen trees, which are only altered states of the live old tree, become part of the forest floor and are eventually incorporated into the forest soil, where myriad organisms and processes make the nutrients stored in the decomposing wood available to the living trees. Further, the changing habitats of the decomposing wood encourage nitrogen fixation to take place by free-living bacteria (Nitrogen fixation is the conversion of atmospheric nitrogen to a form usable by living organisms, such as a tree.) These processes are all part of Nature's rollover accounting system that includes such assets as large dead trees, biological diversity, genetic diversity, and functional diversity, all of which count as reinvestments of biological capital—not economic capital—in the growing forest.

With the foregoing in mind, it is clear that a forest does not—and cannot—function sustainably on economic capital. It requires biophysical capital—leaves, twigs, branches, and the decomposing wood of large fallen trees, including biological diversity, genetic diversity, functional diversity. The reinvestment of such biophysical capital is necessary to maintain the productive capacity of the soil that, in large measure, equates to the long-term productive capacity of the forest. In turn, the productive, sustainable capacity of a forest equates to the long-term economic stability of the timber industry and so human communities.

Be not deceived, however; without balancing withdrawals of products, such as timber, with investments of solar radiation through photosynthesis and biophysical reinvestments of soil elements and decomposing wood, both biophysical interest *and* principal are spent, which inevitably means that economic productivity must eventually decline.

If those who caretake a forest are concerned with the productive capacity of the topsoil, as they must of necessity be, they need to accept the lessons of history. One of the most distinctive historical lessons might be that the birth of agriculture caused civilizations to rise, whereas abusive agricultural practices—based on overexploitation due to flawed, linear, economic thinking—destroyed the topsoil and fostered the collapse and extinction of some of those same civilizations.

History is replete with lessons pointing out that once the sustainable, productive capacity of soil is destroyed, it takes many human lifetimes to replace it. And yet, with all the glaring lessons of history spread before us around the world, we insist on walking the historical path of abusing the soil.

Consequently, the resilience of forested sites following a human-caused disturbance (such as clear-cutting or salvage logging) is at least partly related to the ability of the soil to retain nutrients and water and to maintain its structural and functional integrity during the period in which plants—and trees—are becoming reestablished. Beyond that, the sustainable fertility of the soil is reflected in the productive growth of a forest and the quality of the timber available to harvested on a sustainable basis—sort of a carbon economy.

Abstract

We examine the struggle of the Kayapo indigenous people to protect their constitutional rights over the 40 years since the frontier of settlement and resource extraction exploded around their territories in the highly threatened southeastern Amazon of Brazil. We explore conditions that enable and threaten the Kayapo's continued success in thwarting deforestation and we identify strategies for continued protection. We show that 21st century alliances of the Kayapo with conservation NGOs have enabled protection of over 9 million ha of their contiguous ratified territories. Satellite analysis of Kayapo territory between 2001 and 2019 reveals significant correlation between the location of deforestation hotspots and the presence/absence of NGO investment with Kayapo communities. Key to success has been the development of scalable resource management and income generation activities with Kayapo communities, and strengthening of Kayapo territorial surveillance and control that is essential in the absence of government enforcement of indigenous land rights. Conservation NGOs enabled Kayapo communities to set up their own indigenous NGOs that are critical to build capacity for managing territories sustainably. It is philanthropic investment into the Kayapo over the past two decades that has made the difference between protection and rampant invasion and degradation of Kayapo territories.

Introduction and Background

The Xingu River arises in the woodland-savanna and transitional semi-deciduous forest of northern Mato Grosso and flows north through high moist forest of Pará for 2700 km to empty in the Amazon. A clear water river, it drains a landscape of ancient crystalline Precambrian shield. The Xingu basin covers 51 million ha, of which ~20 million ha is officially recognized indigenous land, while another 8 million ha is protected areas (Campanili, 2012).

The 280,000 km² of indigenous lands and protected areas of the Xingu river basin form a continuous forest corridor larger than the United Kingdom, inhabited by 25 indigenous peoples and traditional riverine families. Immersed in the one of the world's most intense deforestation zones in Pará and Mato Grosso states, the Xingu indigenous lands and protected areas network demonstrate how Brazilian government policy had been working to reduce Amazon deforestation. This progress is regressing due to infrastructure projects, mines, intensifying illegal logging and gold mining, worsening lack of governance, emerging climate change impacts and government proposals to weaken indigenous land rights. This despite the global significance of these natural ecosystems for climate change mitigation, biodiversity conservation and the preservation of traditional cultures.

The Xingu basin has been continuously occupied over at least the last 1200–1500 years (Balée, 1989; Heckenberger et al., 2008). Kayapo fleeing colonists, gold miners, rubber tappers and missionaries occupied the still relatively isolated middle Xingu in the first half of the 19th century. Intensive occupation of the basin only began in the 1970s, with the construction of highways through the basin and the arrival of colonists from southern Brazil. The middle and upper Xingu region has undergone the typical "boom and bust" cycle of frontier occupation and has become a major cattle and soy-producing region such that today, some 1 million people live in 35 counties throughout the basin (Campanili, 2012; Rodrigues et al., 2009).

The official recognition of the Xingu Indigenous Lands and Protected Areas from the late 1940s to 2008, is a product of regional conflicts over land and natural resources and the strategies of indigenous and local communities to both resist and accommodate successive frontiers. The 1988 Constitution recognized indigenous groups' right to maintain traditional cultures permanently, granting them permanent and exclusive usufruct rights over their traditional lands (República Federatva do

Brasil, 1988; Santilli, 1991) and became the basis for large-scale demarcation of indigenous territories. In numerous local struggles and in the forum of national law and policy, indigenous peoples successfully gained recognition of their rights to their traditional lands and now control over 20% of the Amazon.

From the late 1980s the relations between Xingu indigenous groups and the national society changed radically. Mato Grosso and southern Para rapidly became major timber, soy and cattle producing regions, surrounding indigenous territories with agriculture, ranches, roads and towns (Mertens et al., 2004). Regional cities became accessible. Up until this time, FUNAI, the federal government Indian Agency mandated to uphold indigenous rights, had mediated and largely controlled all interactions with the outside world. But with shrinking budgets and diminished capacity, FUNAI decentralized services and some indigenous groups developed independent relations with outsiders. Pressure from outsiders on the natural resources of indigenous territories increased dramatically, as did internal demand for industrialized goods and technology. With increased dependence on manufactured goods and health care, semi-nomadic groups like the Kayapo became sedentary.

The reality faced by indigenous peoples of the Xingu is that enforcement of protected areas and indigenous territories by government authorities went from inadequate (Ferreira et al., 2014) to nonexistent in 2019. Although at a much lower rate than in surrounding lands, deforestation, forest degradation and invasion of Xingu protected areas and indigenous lands by loggers, gold miners and land grabbers has been on the upswing over the past decade (Azevedo-Ramos and Moutinho, 2018; Venâncio et al., 2018).

Conservation Significance of Kayapo Territories

Much of the 20 million ha of the Xingu basin indigenous territories is covered in near intact Amazon primary forest: part of the world's most biodiverse terrestrial ecosystem that is large enough to maintain a full complement of floral and faunal species diversity and rainfall regimes (Benchimol and Peres, 2015; Ewers et al., 2017; Gibson et al., 2011; Jones et al., 2019; Laurance et al., 2006; Michalski et al., 2007).

The 10,600,000 ha block of ratified indigenous territory of the Kayapo is of particular conservation value because of its vast size and interdigitation of both closed-canopy Amazonian forest and central Brazilian savanna or *cerrado*. Of critical conservation significance, Kayapo territory is likely large enough to protect regeneration processes of primary forest tree species (ter Steege et al., 2015). Most primary forest tree species occur locally at very low densities but maintain large absolute populations sizes over large areas (Pitman et al., 1999) and most tree species depend on co-evolved animal vectors for pollination and seed dispersal across large inter-individual distances. Small areas do not contain animal vector populations sufficient for regeneration of many forest tree species over the long term (Ewers et al., 2017; Laurance et al., 2006; ter Steege et al., 2015). The dauntingly intricate web of interdependence among Amazonian species requires large areas to function and persist.

Surveys have shown that much of Kayapo territory remains largely undisturbed as evidenced by population densities of some of the more vulnerable vertebrate species found in Amazonian forests. Large-bodied game species, which are preferred by local peoples throughout the Amazon, are abundant within the hunting range of Kayapo communities. The relatively high densities of game animals (that also include large cracid birds, several monkey species, lowland tapir, giant armadillo and white-lipped peccary) indicate an ecosystem that is little impacted by hunting because non-hunted areas predominate. Indeed, no other large forest reserve in southeastern Amazonia safeguards a full complement of disturbance-sensitive wildlife and the entire vegetation transition from open savanna (*cerrado*) to close-canopy forests (Zimmerman et al., 2001).

Kayapo lands and the contiguous 2.8 million-ha Xingu Indigenous Park to the south protect more than 400 km of the Xingu river from degradation by deforestation, pollution and over-fishing. Preliminary surveys indicate that as many as 1500 fish species inhabit the Xingu River. Fish are the most important source of protein for local people of the Xingu. Sixteen species of fish are considered endemic to the Xingu as they have only been collected from this watershed (Perez, 2015).

Consolidation of the Xingu Corridor is the only remaining possibility for conserving the last large, intact forest of the southeastern Amazon, and maintaining the connectivity of this ecoregion with the western Amazon. Kayapo lands play a particularly important role in the Xingu corridor because of their multilandscape size under the control of a single ethnic group that is on its way to acquiring the skills needed for protected areas management. In addition to biodiversity conservation, the Xingu corridor contributes substantially to maintaining rainfall regimes and carbon stocks of global importance (Gibson et al., 2011; Sakschewski et al., 2016; Soares-Filho et al., 2010; Walker et al., 2014; Leite-Filho et al., 2019).

Warrior Tradition and Land Gain: The Kayapo

Most Kayapo groups were first contacted in the 1950s and 1960s and inhabited widely dispersed settlements. Sub-groups following different chiefs were subject to ongoing internal feuds and regularly raided regional Brazilian settlements for trade goods, particularly firearms, and captives (Verswijver, 1992). While many sub-groups were decimated by epidemics, "contact" with the surrounding society was shaped by Kayapo strategies to access outsiders' goods for their own ends (Gordon, 2003; Verswijver, 1992). Their pro-active warrior attitude combined with well-developed political and social organization served the Kayapo well to secure legal recognition of their territory and defend it from invasions during the 1980s and 1990s.

Through the 1980s and 1990s the Kayapo repeatedly staged highly visible demonstrations, blocked roads, took hostages and expelled gold miners and ranchers from their territory in the process of winning official recognition of their land rights (Turner, 2000). The result of this aggression was official ratification and demarcation of a block of five contiguous indigenous territories (TI) of the Kayapo that span 10,598,616 ha (~106,000 km²): TI Kayapo, TI Bau, TI Mekranoti, TI Badjonkore and TI Capoto/Jarina. At the same time, nearly all Kayapo chiefs negotiated deals with illegal mahogany loggers and in a few cases in the east, with gold miners. In the early 2000s, with mahogany stocks in decline and ramped up NGO investment in conservation and development programs, most, but not all, Kayapo ceased selling logging concessions in their territory. Today some 10,000 Kayapo live in more than 80 communities and small family settlements.

Alliance with Conservation NGOs

In the struggle to protect their lands, the objectives of Amazonian indigenous peoples coincide with a conservation mission of preserving biodiversity and natural ecosystems. Indigenous Amazonians repeatedly assert a fundamental interdependence between cultural identity and territory. Indigenous “traditional knowledge” of forest ecology and the grounding of culture and identity in territory represent a distinctly different world view from that of Western culture and science. While Western science concerns itself with the natural world ruled by material forces and not the cultural realm of values, conventions and concepts, Amazonian indigenous societies include animals, plants, and other natural phenomena in the domain of culture and society (Viveiros de Castro, 1998; Descola, 1994; West, 2005). Indigenous resource knowledge arises from mutual recognition, active communication and exchanges among people, animals, plants, geographic features, spirits, and the dead conceived as actors in the same socio-cosmological networks. Indeed, sustainability of indigenous territories cannot be conceived or measured in purely ecological or economic terms; rather there is also a question of the viability and vitality of cultures (Schwartzman et al., 2013). The Kayapo fight to protect their culture, their livelihoods and very existence. Their goal overlaps with the conservation community in the need to protect what remains of the world’s richest terrestrial ecosystem.

In 1992, at the request of leaders of the Kayapo village of A’Ukre, the international conservation NGO Conservation International (CI) enabled the founding of a biological research station as an income alternative to mahogany logging. The community declared 10,000 ha off-limits to hunting and logging in exchange for fees from researchers and training of Kayapo assistants, with benefits distributed equitably in the community—unlike mahogany payments which were controlled by chiefs. The research station was the Kayapo’s first exposure to a subculture of outside society that places high value on traditional indigenous knowledge, culture and ecosystem protection services and was not seeking exploitation for financial gain. Researchers and NGO personnel offered an alternative development vision to the community of A’Ukre that was based on sustainable resource management and forest conservation (Zimmerman et al., 2001).

The success of the research station to benefit the community equitably while conserving a highly valuable undisturbed population of mahogany trees (*Swietenia macrophylla*) that were under intense pressure to log led Conservation International (CI) to convene a series of meetings over a 6-year period with Kayapo leaders from the entire block of Kayapo territory. The purpose was to: (i) present and discuss the idea of a Kayapo-conservation NGO alliance with the objective of strengthening Kayapo capacity for sustainable resource management, economic autonomy and territorial control, and; (ii) provide opportunity for Kayapo leaders to reinforce traditional bonds and unite under a single vision for the future. By 2006, the majority of Kayapo leaders chose to ally with the NGOs and reject illegal activity and predatory resource exploitation on their land.

With consensus reached on the goal of a Kayapo-NGO alliance, CI helped the Kayapo to establish their own local NGOs: Instituto Raoni (IR) formed in 2001 and based in Peixoto de Azevedo, Mato Grosso to represent the south-western Kayapo; the Associação Floresta Protegida (Protected Forest Association) (AFP) formed in 2002 and based in Tucuma, Para, to represent the north-eastern Kayapo, and Instituto Kabu (IK) formed in 2008 and based in Novo Progresso, Para, to represent the northwestern Kayapo. No local NGO was set up to represent the southeastern Kayapo because by the time CI arrived on the scene, the mid- to south-eastern Kayapo centered at their main community of Gorotire had fallen firmly into the clutches of the illegal sector. The Gorotire Kayapo were the first to face the main onslaught of the frontier during the 1980s. After valiant and successful land battles but facing hordes of gold miners, the Gorotire Kayapo were drawn into illegal resource extraction on their land in collusion with local frontier society.

Kayapo NGOs have fought hard to resist frontier pressure on their land and resources. As the frontier of roads, ranching and towns consolidated around them over the past three decades, the Kayapo gained much greater access to towns and manufactured goods. The young generation of Kayapo especially seeks technology and education. Today, Kayapo face a choice between unsustainable, illegal but in the short term high-value activities, and lower-value conservation-based enterprises that take longer to develop but are sustainable and legal. Kayapo NGOs have been developing a successful portfolio of nontimber forest product and service enterprises with their communities that fit with Kayapo culture and that generate equitably distributed benefits:

- **Brazil nut:** In 2019 32 communities participated in the harvest and sale of Brazil nut to the domestic food industry for a favorable price brokered by their NGOs. Kayapo NGOs subsidize harvest and transportation costs. Brazil nut sales now generate over US \$350,000 per year for community members.
- **Cumaru nut (tonka bean).** As with Brazil nut, cumaru is a fruit produced by a primary forest tree that is harvested by the Kayapo in natural forest after falling to the ground. The United Kingdom cosmetics company Lush buys 100% of the Kayapo cumaru harvest. Cumaru sales now generate over US\$45,000 per year for Kayapo harvesters of 24 communities.

- *International field course*: the Pinkaiti field station of the community of A'Ukre hosts two international university field courses every summer in partnership with Brazilian universities. This generates about US\$25,000 per year for this community.
- *Catch-and-release sportfishing*: the northeastern Kayapo NGO AFP partners with sport fishing company "Untamed Angling" to host a catch-and-release sport fishing enterprise based out of Kendjam village on the Iriri river. This enterprise generated US \$50,000 in 2019 for the two communities on the Iriri river. The AFP and Untamed Angling are opening a second sport fishing and ecotourism enterprise on the Xingu river that will serve six communities located there.
- *Handicrafts*: the sale of handicrafts including bead jewelry and paintings generated over US\$40,000 for Kayapo communities in 2019.

Sustainable income alternatives are now generating close to half a million dollars per year for Kayapo communities of the NGO alliance. Although reliable markets for these nontimber products and services exist, these enterprises are not yet 100% financially sustainable and require business management and administration subsidy.

The local Kayapo NGOs organize border surveillance. Guard posts established at key entry points have proven effective at blocking invasions by loggers, gold miners and ranchers. Government enforcement of Kayapo indigenous land rights ended in 2019 making the Kayapo surveillance program even more crucial for territorial protection.

The criterion for a Kayapo community to receive philanthropic investment is no involvement in illegal activity. The monetary value of payments from loggers and gold miners to Kayapo individuals is higher in the short term than from conservation enterprises and requires no Kayapo labor. However, in addition to being unsustainable and leading inevitably to severe cultural and environmental degradation as well as territorial loss, illicit activities do not fulfill egalitarian values of Kayapo society. Loggers and gold miners negotiate concessions on Kayapo land with chiefs and generally do not distribute payments among community members; whereas NGO supported non-timber forest product enterprises and border guard posts generate equal opportunity work and equitably distributed benefits, as is compatible with Kayapo culture. Communities will not support individuals proposing to take them down an illicit unsustainable path when sustainable options that materially benefit all are available.

Hotspot Analysis Demonstrates Success of Kayapo NGO Alliance

The overarching goal of the Kayapo-conservation NGO alliance is to empower the Kayapo to defend their constitutional rights, protect their ecologically intact territories and develop sustainable economic autonomy within the lawless frontier zone of the southeastern Amazon. Kayapo NGOs and their partners have worked over almost two decades to grow and diversify a portfolio of sustainable conservation-based enterprise, generate equitably distributed benefits, and strengthen territorial monitoring and surveillance over a vast roadless area demarcated by some 2000 km of border.

Other factors besides money figure in Kayapo development decisions. Perhaps most highly of all, the Kayapo value protecting their constitutional right to exclusive occupation and control over their territory; their concern is the survival of their culture and descendants. Once they gain a foothold, loggers and gold miners quickly overwhelm Kayapo traditional governance systems and take control of an area. The eastern Kayapo were drawn into the illicit frontier economy in the 1980s and 1990s having had no experience with these activities and no support to develop economic alternatives or to foresee the inevitable and irreversibly destructive consequences of predatory logging and gold mining. Immersed in a region where lawlessness and corruption prevail, they have lost control over roughly 1.2 million ha of their territory in the east (Fig. 1) which is now a no-man's land dominated by gold miners, loggers and other illegal actors. The Kayapo living in these eastern communities depend on these actors to provide the manufactured goods they have come to need. Most rivers in this area are choked with mud and polluted by mercury used in gold mining. Forest is degraded by logging which removes most of the big, old growth primary forest trees so pivotal to the overall ecology of this biome. This opens these once resilient forests to fire. Traditional culture breaks down in lockstep with environmental degradation and the introduction by loggers and miners of alcohol, drugs and prostitution.

The intact environmental and social conditions of NGO-allied Kayapo territory contrast starkly with the breakdown in the east. As of 2019, the total Kayapo population numbers almost 10,000 people living in 82 communities and small family settlements located throughout their 10.6 million-ha block of territory (Fig. 1). Of this land, 89%, or 9,400,000 ha, is controlled by 61% of the Kayapo population who live in 48 communities and small settlements that have allied with the NGOs to pursue sustainable economic autonomy and territorial control (Fig. 1). Ninety percent of the approximately 4000 Kayapo living in 34 communities and small family settlements involved with the illicit frontier economy reside in the 1,200,000-ha band of eastern territory that fell to the frontier of predatory resource extraction before the arrival of NGOs (Fig. 1) or before NGO programs were developed enough to help the Kayapo bar the intense wave of illegal activity resurgent in the region after 2010.

Deforestation Hot Spots Analysis

We analyzed the Kayapo territory for loss events using Hansen et al.'s (2013) global forest change 2000–18 imagery from the Google Earth Engine data catalog and GLAD alert imagery (Hansen et al., 2013) for 2019. Loss events were extracted and tallied for each year within the time series for the Kayapo territory and the respective east and west boundaries. Loss events found within 5 km of a village or in naturally occurring non-forest landscapes (i.e., cerrado/savanna, rock outcrops) were omitted.

Fig. 1 The block of five contiguous Kayapo indigenous territories (TI) from space (TI Kayapo, TI Bau, TI Mekragnoti, TI Capoto/Jarina, TI Badjonkore). The light colored non-forest in Kayapo territory denotes naturally occurring savanna-woodland on plateaus and outcrops of Brazilian shield rock. The locations of villages with more than 50 people are shown. Red outlines 9.4 million ha of Kayapo territory that is represented by a local Kayapo NGO and receives outside conservation and development investment. Blue outlines 1.2 million ha of Kayapo territory that receives no NGO investment. Alerts indicate forest cover loss.

An optimized hot spot analysis was performed using ArcGIS® Desktop (ESRI, 2018). The optimized hot spot tool uses the Getis-Ord Gi statistic (Getis and Ord, 1992; Ord and Getis, 1995) to create a map of statistically significant hot (areas of higher incidence) and cold (areas of low incidence) spots given the event points. The focus is on presence or absence rather than measured attributes associated with each point. The hot spot analysis was performed for all of the loss events within the Kayapo territory from 2001 to 2019.

Hot Spot Analysis Results

From space we observe significant correlation between the location of deforestation hotspots and the presence/absence of NGO investment with Kayapo communities (Figs. 1–3). The absolute number of loss events are greater for the western zone for most years. However, the western zone is 9,423,000 ha, approximately eight times the area of the eastern zone (1,200,000 ha). When this is taken into account looking at the loss events per hectare, we see that the eastern zone has much greater densities of loss events per hectare (Fig. 3).

Discussion

Indigenous territories are known to have formed effective barriers to frontier expansion and deforestation (Nelson and Chomitz, 2009; Nepstad et al., 2006; Nolte et al., 2013; Pffaf and Robalino, 2013). Deforestation in the Xingu Basin is heavily concentrated outside of the indigenous lands and protected areas. Of the ~10 million ha deforested in the basin through 2010, 91% was outside of protected areas, 3% was in indigenous lands, 1.4% in Federal protected areas and 4% in state protected areas (Campanili, 2012).

Fig. 2 Hot spot analysis of all forest cover loss events across Kayapo territory from 2001 to 2019. The map shows statistically significant areas of higher hot spot incidence (in red) given the event points. Hot spots indicate deforestation events.

Fig. 3 Forest loss event densities for the east and west sectors of Kayapo territory. The blue bars are the eastern (no NGO investment) Kayapo territory loss events per hectare per year. The red bars are the western (NGO investment) Kayapo territory loss events per hectare per year.

However, the Xingu basin spans the most high-deforestation region of the Amazon frontier and pressure on indigenous territories and protected areas has ramped up dramatically over the past decade. There was a 54% increase in overall deforestation in the Xingu basin during the first 2 months of 2019 compared with the same period in 2018 (Siradx, 2019a). The number of fire hotspots in the Xingu basin detected between July and August 2019 increased 271% from the same period in 2018 with deforestation in indigenous territories increasing 158% during the summer of 2019 compared to 2018 (Siradx, 2019b). Intense activity by illegal loggers and gold miners combined with lack of law enforcement by government authorities has led to significant losses along the eastern band of Kayapo territory (Fig. 1). Gold mining and logging continue to expand in the non-NGO represented areas of eastern Kayapo territory (Figs. 1–3). Beginning in about 2015, over 1500 ha were being lost annually to gold miners in eastern Kayapo territory.

The relative lack of deforestation and degradation throughout more than 9 million ha of Kayapo territory to the west compared to the heavily degraded 1.2 million-ha eastern band of Kayapo territory can be explained by philanthropic investment into Kayapo empowerment for territorial control. Where Kayapo communities receive help to monitor and control their territory, develop equitable and sustainable sources of income and gain insight into threats, their borders largely hold and forest remains largely intact. Kayapo territory that receives no conservation and development investment is being heavily invaded by gold mining and fire in forest degraded by logging (Figs. 1–3). A low density of hot spot alerts overlaps almost exactly with Kayapo territory that is represented by and receives program support from Kayapo indigenous NGOs that in turn are supported by international conservation NGOs (Figs. 1–3). This pattern cannot be explained by cultural differences as the eastern and western Kayapo belong to the same ethnic group whom share the same history (Verswijver, 2018); nor can it be explained by distribution of gold and timber which is found throughout Kayapo territory. Also, access and exposure to the frontier is similar across all Kayapo territory: there is nowhere in Kayapo territory that loggers and gold miners cannot reach.

Governance in the southeastern Amazon region has always been weak. After gold mining resurged in the eastern region of Kayapo territory in about 2013, the federal Ministry of Environment (IBAMA) performed helicopter supported enforcement operations designed to deter goldmining and logging. Between 2015 and 2018 IBAMA executed 12 raids on illegal goldmining and logging afflicting Kayapo territory. Although several millions of dollars of illegal heavy equipment was destroyed and dozens were arrested, an under resourced IBAMA was unable to apply operations with enough frequency to shut down illegal activity completely. Nevertheless, there was a deterrence effect and goldminers and loggers were hesitant to enter new areas.

In 2019, with government enforcement operations halted, loggers and goldminers became emboldened to enter Kayapo land. The three Kayapo NGOs which together are responsible for protecting over 9 million ha of Kayapo territory have responded with a ramped up territorial surveillance and more border guard posts. This territorial surveillance program depends in large part on international philanthropy.

Conclusion

Kayapo territories are a critical source of ecosystem services—biodiversity conservation, carbon storage, watershed protection and maintenance of rainfall regimes. As with other indigenous peoples of the Xingu region, the Kayapo clearly and consistently affirm that their territory, cultural identity and traditional knowledge are mutually interdependent. Self-reflexive understanding and valuing of traditional culture and knowledge as distinct from Western values and science, including dialogue between Western science and traditional knowledge, are key conditions for the sustainability of these territories.

Creation of protected natural reserves and legal recognition of indigenous territories has largely formed a barrier to deforestation until now; but illegal logging and gold mining remain pervasive threats and deforestation rates are intensifying. NGO investment has been effective in enabling the Kayapo to maintain control over almost 90% of their vast territory, mostly by supporting their local indigenous institutions (NGOs) to develop sustainable enterprises and manage and control their territories. Economic alternatives to logging and goldmining have clearly had an impact but need to develop further in order to fully meet community demand for income and market access. Kayapo NGOs have responded to intensifying threats by ramping up their territorial surveillance programs and establishing border guard posts that have proven effective for controlling access to their territory. These projects are scalable but will require continued philanthropic investment to grow as well as continued capacity building for community members to effectively manage local enterprises. In essence, outside support for Kayapo NGOs and their programs can be viewed as payment for ecosystem services. The Kayapo have demonstrated that partnerships between indigenous people of the Amazon and conservation organizations can achieve protection of primary forest and concomitant empowerment of indigenous rights.

Abstract

Forest disturbances are among the most spectacular manifestations of ecological change. They are the subjects of countless scientific studies, newspaper headlines, local and national legislation, and international initiatives. Despite the ubiquity of disturbances in forests globally, many central questions remain unresolved and many policy strategies are at odds with contemporary ecological understanding. Here we consider the causes and consequences of forest disturbances and discuss related ecosystem management. While throughout much of the history of the science of ecology, disturbances were considered aberrations or disruptions to functioning ecosystems, there is now clear recognition that disturbances are integral components of functioning ecosystems, representing a necessary part of the ecological whole. Although disturbances, especially large and severe ones, can be challenging from a management perspective, it is often possible to incorporate disturbances into management plans that provide multiple ecosystem services. Eliminating disturbances is neither possible, nor always desirable. Although passive management of all disturbed forests is not necessarily feasible, allowing disturbances, even large ones, to shape some forest ecosystems may promote ecological resilience in the face of climatic and environmental change.

Introduction—What are Disturbances?

Forest disturbances are among the most spectacular manifestations of ecological change. They are the subjects of countless scientific studies, newspaper headlines, local and national legislation, and international initiatives. Despite the ubiquity of disturbances in forests globally, many central questions remain unresolved and many policy strategies are at odds with contemporary ecological understanding of disturbance behavior, likelihood, effects, and roles in long-term, basic ecosystem functioning. Here we consider the causes and consequences of forest disturbances and discuss related ecosystem management.

Various definitions of forest disturbances have been proposed, but one of the most enduring and simple definitions is still one of the most useful. In 1985, White and Pickett defined a disturbance as “any *relatively discrete* event in time that disrupts ecosystem, community or population structure and *changes* resources, substrate availability, or the physical environment” (italics added). The fact that disturbances are limited to *relatively discrete* events implies that climate and climate change usually are not considered disturbances in and of themselves. However, the indirect effects of climate and climate change, such as wildfires and insect outbreaks, are considered disturbances. The scientific literature is inconsistent in categorizing drought as a disturbance, in part because droughts vary in their temporal discreteness and their ecological effects. For the purpose of this chapter, we consider drought as a climatic effect rather than a disturbance. The second part of White and Pickett’s definition emphasizes a *change* in resource availability or the physical environment. All disturbances change affected ecosystems, by the initial disturbance (e.g., a wildfire) as well as by any subsequent related disturbances (e.g., insect population increases due to downed wood or post-disturbance logging). Such linked and compounded disturbances are discussed later in the chapter. Both criteria for a disturbance—temporal discreteness and resource change—depend on the scale of investigation. Increases in resources via

fine-scale tree mortality may be significant for processes operating at fine scales, but insignificant at broader (e.g., regional) scales where patterns may be shaped primarily by topography and climate. Conversely, the effects of large disturbances can be contingent on fine-scale pre-disturbance heterogeneity (e.g., Mietkiewicz et al., 2018). Importantly, we underscore that conceptualizing disturbances as changing stand structure and resource availability emphasizes the fact that disturbances normally do not destroy ecosystems. Instead, disturbances abruptly change ecosystems in ways that are often significant and not always predictable.

Disturbances are complex and each event is seemingly unique due to the nuanced interplay of factors involved. Despite this, there are commonalities among disturbances that have led to classification systems based upon various attributes. The most common categories are based on the agent (fire, insect, wind, avalanche, etc.), source (natural vs. anthropogenic), origin (endogenous vs. exogenous), affected strata (canopy vs. understory), and status (abiotic vs. biotic). Grouping disturbance events by commonalities allows for cross-system comparisons, even if it glosses over complexities in each event as well as the interplay between apparent opposites. For example, natural (e.g., insect outbreaks) and anthropogenic (e.g., logging) disturbances differ in their ecological effects and in the degree to which forest species are adapted to them. However, during the Anthropocene, most so-called natural disturbances are influenced by anthropogenic climate change, which can affect the disturbance agent as well as the resistance of trees to that agent. Similarly, the classic dichotomy of endogenous versus exogenous disturbances is limited by the recognition that the effect of so-called exogenous disturbances is determined by ecosystem structure and composition (e.g., tree species vary in their susceptibility to wind damage), while so-called endogenous processes are shaped by past disturbances (e.g., fine-scale regeneration patterns can be affected by the spatial distribution of coarse woody debris, which reflects the history of past disturbance). Although some disturbances do affect only the canopy or the understory of a forest, most affect both to varying degrees. For example, emphasizing that a windstorm kills canopy trees may be correct, but it also may overlook the damage or mortality to understory trees. Similarly, although it is useful to contrast fires and other disturbances as being either low or high severity, the recognition that many wildfires have mixed severity components underscores the ecological importance of even few survivors in otherwise high-severity events.

The cumulative disturbance types and their characteristics that affect a particular area are referred to as a disturbance regime, which can be described by the frequency, return interval, rotation period, size, intensity, and severity of disturbances (Pickett and White, 1985). Thus, disturbance regimes vary with the temporal and spatial scales in question (Clark, 1989). Although it is clear that climate change is affecting forest disturbances in general, considering specific attributes of disturbance regimes allows us to more precisely identify and understand the aspects of disturbances that are changing. For example, although recent outbreaks of mountain pine beetle (*Dendroctonus ponderosae*) in the western US are clearly influenced by climatic conditions (Hart et al., 2014), very extensive and synchronous outbreaks are not necessarily unprecedented over the past centuries (Jarvis and Kulakowski, 2015). This recognition and specificity allows us to focus on the effects of climate on the *intensity* of outbreaks rather than their *size*. In contrast, although wildfires have shaped forests of the western United States for millennia, recent climate change has increased the *intensity* and *size* of fires in some forests (Running, 2006; Westerling, 2016). In other cases, wholly new disturbance phenomena are emerging, such as root freezing as a result of snow loss in high latitudes, that cause mass mortality over extensive areas (Buma et al., 2017b). Thus, considering the specific attributes of disturbance regimes facilitates more nuanced comparisons and analyses—including of possible thresholds, tipping points, and alternate stable states.

Why, When, and Where Do Disturbances Happen?

Disturbances, in some sense, can be seen as entropy reasserting itself. Ecosystems are comprised of organisms in highly ordered and energetic states; disturbances disrupt that state. Forests are an excellent example of such a state—long lived organisms, with considerable chemical energy contained in their structures, in complex stratified arrangement (Lowman and Rinker, 2004). Fires are an example of the chemical energy stored in those bonds being re-released as heat; windstorms are an example of the orderly structure being reconfigured.

What is the Limiting Factor?

While each disturbance process (e.g., fire, wind, landslides) and each disturbance itself has its own characteristics and mechanisms, generally speaking, the occurrence of a forest disturbance depends on the confluence of three factors: sufficient biomass to be disturbed, some instigating factor to initiate a disturbance event, and external conditions that can sustain the disturbance beyond the initial mortality event.

Sufficient biomass—The amount of live and dead material in a forest is key for the propagation and effects of a disturbance to be recognized as such. This biomass must also be structured in a way as to be exposed to a given disturbance type. While conditions capable of causing tree mortality may be present, if a tree or forest are not developed to a susceptible structural stage, that disturbance will not occur or will not propagate. For example, very young trees do not typically have the structure (rigid stems, substantial height) to be disturbed by windstorms. Similarly, the suitability of a given tree to bark beetle infestation is restricted by the size of the tree (e.g., Kärvelo et al., 2016). At broader scales, a very sparsely forested area may not have the tree density necessary to carry a fire (Song and Lee, 2017). An important caveat is that extreme climate or weather can relax the structural requirements for disturbances of trees (e.g., warm temperatures can make small diameter trees susceptible to bark beetle infestation) or landscapes (e.g., strong winds can render a landscape functionally connected for fire spread).

Instigating factor—Instigating factors are required for a disturbance. For fires, an ignition source; for landslides, the initial slope failure. While for each disturbance type this instigating factor is different, each has the characteristic of starting a process that is, in many cases, at least partially self-sustaining. In fires, the initial ignition (perhaps caused by lightning) causes further ignition of individuals, spreading the fire. In windstorms, the first initial tree failure (blowdown or snapping) allows for more intense wind to enter a stand, leading to increased stress on neighboring trees and an expanding blowdown patch.

External conditions—Given sufficient biomass and structure and the instigating event, the proper conditions must be present to drive a disturbance event beyond initial mortality. As before, negative examples are illustrative. In southeast Alaska, sufficient biomass is present for extremely large wildfires. At >500 Mg/ha density, extremely complex crowns with substantial ladder fuels, and very homogenous spatial arrangement, the forests could carry very large and intense fires. Lighting is infrequent, but not nonexistent, and anthropogenic ignitions are present, as evidenced by occasional small events. Yet there is no evidence of large, severe fires in the northern part of this region since the last Glacial maximum (~12,000 years). The lack of a summer dry period is the likely reason—the region receives around 20% of its rainfall in the driest quarter, meaning fuels have no opportunity to reach a condition suitable to sustain large fires. As a result, while sufficient biomass and structure exist, conditions suitable for fires are rare. The situation for windstorms is quite different, however – high winds are relatively common and correspond with wet autumn storms that soften soil, increasing tree susceptibility. As a result, wind mortality is the most common disturbance event in the region.

Frequency of disturbances

The frequency of disturbances varies spatially and temporally and depends on the limiting factors discussed above. A recent fire-scale (30 m) quantification across the entire North American continent found that some forested ecoregions were disturbed at rates <0.1% per year, while other disturbance rates in other ecoregions were >10% per year (Buma et al., 2017a). At the global scale, forest disturbance patterns are variable but high disturbance activity is most correlated with climate (Sommerfeld et al., 2018), though the climate-fire relationship is weaker in areas of high anthropogenic pressures, potentially a signal of human impacts on ignitions (e.g., suppression or intentional burning) or biomass (Abatzoglou et al., 2018; Syphard et al., 2017).

Understanding past and current drivers of the frequency of disturbances enables predictions of climate change or anthropogenically driven effects. For example, in Yellowstone National Park, weather and climate conditions conducive to fires are generally assumed to be the primary driver of large fires. This leads to expectations of much more frequent fires in the future as conditions more frequently approximate those that have been associated with historically severe fire years (Westerling et al., 2011)—or at least until biomass limitation reduces fire extents. In contrast, landslides remain a challenging disturbance to anticipate (especially in terms of frequency) because they are generally limited by initiation—in other words, conditions that are associated with landslides are not uncommon (Caine, 1980), and sufficient biomass (and soil mass) is similarly common, yet actual initiation and subsequent disturbance are infrequent and remains difficult to predict (Zhu et al., 2018) due to the fine spatial scales and uncertainties involved. As always in disturbance ecology, the limiting factor depends on the scale of investigation. Very large, infrequent fires are often limited by broad scale weather and climate, whereas smaller fires in the same area may be more limited by ignition frequency.

Interacting Disturbances

As climate is increasing the frequency and extent of disturbances such as wildfire, bark beetle outbreaks, and windstorms, forests and other ecosystems are increasingly being affected by multiple disturbances over relatively short periods. Potential interactions among disturbances can affect ecosystem patterns and processes, including susceptibility to subsequent disturbances. Disturbances exert a strong control on subsequent disturbance probabilities (Buma, 2015; Kulakowski and Veblen, 2015), often by limiting biomass or influencing its structure in such a way as to increase or decrease the likelihood, extent, or severity of a second disturbance event (Seidl et al., 2016). In fact, research over the past decades has highlighted the fact that disturbances do not act in isolation, but rather interact with other disturbances to shape ecological structure and function. For example, fires have been shown to reduce subsequent susceptibility of forest to outbreaks of some bark beetles by reducing tree size following fire (Kulakowski et al., 2003, 2006; Veblen et al., 1994). However, such resistance to disturbances conferred by preceding disturbances may be reduced as climate change increases the intensity of disturbances (Kulakowski et al., 2012). This resistance is dampened because pre-disturbance stand conditions generally become less important in determining the susceptibility of a forest to disturbance as disturbance intensity increases (Turner, 2010).

While in some cases, climate change can dampen the interactions between linked disturbances, in other cases climate can serve as an underlying driver of multiple disturbances in the same landscape. For example, over the past decades, occurrence of large wildfires across the western United States has been driven primarily by warm and dry climate conditions. At the same time, extensive outbreaks of mountain pine beetle across the same region have also primarily been driven by climatic conditions that promote the growth of beetle populations and reduce host resistance. Despite the co-occurrence of these two disturbances in the same landscape (and common assumptions), the current state of knowledge indicates that co-occurrence of wildfires and outbreaks are due to a common climatic driver, rather than interactions between these disturbances (Buma, 2015; Kulakowski and Veblen, 2015; Mietkiewicz and Kulakowski, 2016).

The Disturbance Regime

Disturbance regimes (as introduced above) are the cumulative total of all disturbance types including their severity and frequency, over some period. Disturbance regimes can also be considered for individual disturbance types (e.g., the wind regime). In all cases, it is important to recognize that regimes vary across spatial and temporal scales. For example, protected (leeward slopes) within a region may only experience blowdowns every ~1000 years, or may have never experienced a blowdown. Thus, defining spatial and temporal scales is extremely important when describing a disturbance regime.

Historical range of variability

Many disturbance regimes have characteristic variabilities over discrete periods. Some forested ecosystems have had relatively regular disturbance regimes, at least prior to human intervention (Fulé et al., 1997). Other systems, especially those where disturbance occurrence depends on the confluence of rare initiation events and weather/climatic conditions, have highly variable disturbance return intervals (Schulte and Mladenoff, 2005; Turner et al., 1993). Variability and non-equilibrium processes, even in systems generally considered predictable, is common (Mori, 2011).

Characterizing a disturbance regime is commonly done by defining a historical range of variability (HRV), or the anticipated range of possible disturbance attributes (extent, severity, etc.), return intervals, and types as defined by historical events. The HRV is typically reconstructed via historical records or paleoecological techniques such as tree cores or pollen/sediment cores. While the validity of the HRV is often questionable over long time periods or broad spatial extents (Baker and Williams, 2018), it is still utilized as a useful concept for ecosystem description. Most notably, HRV can be used to assess deviance of an ecosystem from its characteristic behavior as a result of climate change or other human influence.

Deviations from HRV

Rapid changes in disturbance regimes can be caused by alterations to any of the primary limitations on the regime—biomass, ignition, or drivers (e.g., climate). For fires, for example, extensive documentation exists for rapid disturbance regime shifts associated with changing initiation sources (increases or decreases, Fulé et al., 1997; McWethy et al., 2010; Nevle and Bird, 2008), biomass (increasing or decreasing, Coffman et al., 2010; Hiremath and Sundaram, 2005; Keeley and Brennan, 2012), interactions between disturbance legacies (Buma, 2015), and climate conditions becoming more conducive to disturbance propagation (e.g., fire spread, Westerling, 2006). While the latter have received much of the attention of modelers and scientists due to the obvious tie to climate change, the “climate-independent” factors (Pausas and Keeley, 2014) also must be considered alongside rapid climate change as triggers for disturbance regime change in the future.

Disturbances as Integral Components of an Ecosystem

While throughout much of the history of the science of ecology, disturbances were considered aberrations or disruptions to functioning ecosystems (Clements, 1936), there is now clear recognition that disturbances are integral components of normally functioning ecosystems, representing a necessary part of the “ecological whole.” Disturbances have exerted an evolutionary force on species, and species are typically well adapted to the historical disturbance regimes of the ecosystems in which they occur (Pausas and Keeley, 2014). Though there is still debate as to the exact role of disturbances, especially fire, in driving species-level genetic adaptation (Bradshaw et al., 2011; He and Lamont, 2018; Pausas et al., 2017; Poulos et al., 2018), there is little doubt that at the ecosystem scale, disturbances are integral to normal structure and functioning.

Relatively complex structure, both vertically and spatially, is characteristic of forested landscapes. Complex physical and compositional structure is generally positively correlated with biodiversity (Camargo et al., 2018; McElhinny et al., 2005), carbon storage, and long-term resource use efficiency (Curtis and Gough, 2018). Disturbance processes maintain the structure and function of ecosystems, both in terms of habitat heterogeneity and successional stage of those habitats, by creating and responding to landscape heterogeneity and favoring species with disturbance-associated resistance or resilience strategies (Bond and Keeley, 2005). The spatial mosaic of biomes (e.g., forest vs. savannah ecosystems) can be driven by disturbance processes themselves, in addition to factors like climate, soil, and topography (Bond and Keeley, 2005; Dantas et al., 2016).

Within forests, a major function of disturbances is the creation and maintenance of spatial heterogeneity (Fig. 1). Multi-aged landscapes have a variety of characteristic species, structure, and biogeochemical properties (Swanson et al., 2011). This heterogeneity provides an added dimension to the underlying spatial heterogeneity imposed by differences in species composition and physical setting (Donato et al., 2011; Mori et al., 2018). Further complexity is introduced by intermediate or mixed severity disturbances and multiple disturbance types, both of which can vary across space and time (Meigs and Keeton, 2018; Peterson, 2019).

Nutrient Cycling

Nutrient cycling is strongly influenced by forest disturbances shaping nutrient availability and stoichiometry (i.e., ratios of available nutrients) immediately after disturbance and the species composition of the post-disturbance landscape. While considerable work has focused on the effects of disturbances on nutrient cycling immediately post-disturbance, less attention has been paid to the

Fig. 1 Natural disturbances can create spatial heterogeneity (e.g., variation in the amount and arrangement of surviving forest patches or trees) that often promotes biodiversity, primary production, wildlife habitat, hydrogeologic protection, and ecosystem resilience. Routt National Forest, Colorado. Photo: D. Kulakowski.

fundamental role of disturbances in nutrient cycling in the long-term, as a component of the entire ecosystem (Kranabetter et al., 2016).

Nutrient availability and stoichiometric ratios of forests change rapidly post-disturbance on multiple timescales and are strongly mediated by the forest microbiome. While the shifts partially depend on the characteristics of the disturbance event itself (e.g., fire vs. wind), all disturbances have the effect of moving nutrients and carbon from living pools into dead pools, thus making them available for mineralization and ultimately re-uptake, long-term sequestration, or export (Certini, 2005; Santos et al., 2016). Generally, the coupling between nutrient cycles in mature forests is relatively tight; disturbances have the effect of decoupling pathways temporarily (Keiser et al., 2016). For example, nitrogen availability increases either due to mineralization in the event itself (e.g., fire) or decreased uptake, with the magnitude of the effect related to the severity of the disturbance (Nave et al., 2011). At a fundamental level, this provides heterogeneity in the biogeochemical landscape that various species can exploit (Swanson et al., 2011; Townsend et al., 2008).

Species composition shifts associated with disturbances can significantly impact nutrient cycling over longer timespans, perhaps most obviously via favoring species with nitrogen-fixing symbioses. These plant species are typically light demanding, corresponding to a need for higher carbon fixation to offset the cost of their nitrogen-fixing partnerships, and thus often post-disturbance colonizers. For example, in many northern hemisphere forests, *Alnus* species are prevalent in disturbed environments. These species can deliver substantial amounts of nitrogen to ecosystems, and with episodic, disturbance-driven events can drive extraordinarily high levels of nitrogen in forest soils ($23,000 \text{ kg N ha}^{-1}$, Perakis et al., 2011). In forests where N-limitation decreases post-disturbance, the emergence of other biogeochemical limitations (Perakis et al., 2013) are emerging fields of research.

Absence of Disturbance

The fact that disturbances are fundamental components of forest ecosystems is perhaps best exemplified by forests without major disturbance processes. Many forests without occasional disturbances eventually undergo ecosystem retrogression processes—long-term (multi-generational) declines in productivity (Buma and Thompson, 2019) associated with gradual water saturation or nutrient limitation. In cooler forests, paludification (i.e., conversion of forest to peatlands) of forests is common in the absence of disturbance, characterized by the gradual conversion to peatlands with no intermediate aquatic phase. For example, in boreal forests, fires release organically fixed nutrients, decrease thickness of the soil organic matter layer, and results in more rapid decomposition in early successional stands. In old, undisturbed stands, nutrient availability, productivity, and decomposition rates decline, ultimately leading to soil moisture increases, and Sphagnum bogs that can replace the forest (Simard et al., 2007). Disturbance severity is also an important factor, with higher severity fires forestalling paludification and lower severity fires accelerating it. This same relationship of lowered productivity (estimated as lower baseline carbon stocks) exists at broad spatial scales in temperate forests exposed to only wind and landslides (Buma and Thompson, 2019). Soil disruption appears key in the process of maintaining productivity by directly impacting the nutrient cycling patterns discussed above and limiting soil moisture

increases; forest harvest that does not disrupt the soil, much like low-severity fires, can accelerate paludification by decreasing transpiration without also disrupting the thick, organic layer (Renard et al., 2016).

A second driver of lowered productivity is gradually increasing nutrient limitations due to long-term leaching losses or restricted availability, most commonly phosphorus but also nitrogen (Peltzer et al., 2010). Without disruptive disturbance processes to free up parent material for phosphorus and nitrogen (Houlton et al., 2018) or create habitat for strong nitrogen-fixation, inputs of those nutrients (and others) frequently cannot keep pace with losses. Access to nutrients can also be restricted by impermeable soil pan formation or thick, water-rich organic layers. Overall, productivity declines due to nutrient limitations (Peltzer et al., 2010) contribute to declines in tree biodiversity (Wardle et al., 2008) and mycorrhizal diversity (Krüger et al., 2015), though vascular plant diversity overall can increase and some species may specialize in these “retrogressive” forests (Wardle et al., 2008). This highlights the fundamental role that disturbances, especially those that cause soil disruption, have in maintaining productivity. Even high biomass, mature, “climax” forests, in which structure, composition, and biodiversity are shaped by gap-phase dynamics, are generally temporary (though possibly long-lasting) stages in much the same way as are early successional stages—without the occasional disturbance, the landscape will continue to change.

What Happens After Disturbance?

The concept of resilience has become central in discussions of global environmental change. Most generally, resilience refers to the ability of a system to be disturbed without shifting to a different state controlled by different processes (Gunderson, 2000; Holling, 1973). However, the “state” of the system may be defined any number of ways, including by tree size, forest structure (e.g., multiple-aged stands), forest type (e.g., spruce forests), vegetation type (e.g., forests), or even broader categories (Buongiorno et al., 1994; Vogt et al., 1995). Given this breadth of possible criteria, it logically follows that our working definition of resilience affects our assessment of ecological change. The broader the range of conditions that we consider normal, natural, or acceptable, the more resilient we will understand a system to be (Kulakowski et al., 2017). Questions of whether disturbances threaten or promote resilience; whether recent disturbances are unprecedented, or simply infrequent; and what characterizes natural ecosystems require a fundamental and often long-term understanding of ecological dynamics (Johnstone et al., 2016; Peterson, 2000; Shugart, 1984; Turner, 2010). Thus, our understanding of what happens after recent disturbances can be understood not only by observing recent phenomena, but also by contextualizing those processes in terms of long-term ecosystem variability (Buma et al., 2019; Landres et al., 1999). With this broad-scale and long-term view in mind, we turn to the question of what happens after disturbances.

Post-disturbance forest development depends on disturbance severity, pre-disturbance forest structure, and biophysical setting (e.g., Kulakowski et al., 2013; Vacchiano et al., 2014). In many systems, mixed severity events may maximize heterogeneity across the landscape. Stand-replacing disturbances (that leave no or few surviving trees) can create relatively homogenous regenerating forest structure in the decades that follow, unless underlying environmental heterogeneity is substantial (Palmer, 1994; Wohlge-muth et al., 2002) or unless surviving biological legacies drive structural and compositional diversity (DellaSala and Hanson, 2015). Regeneration following such higher severity disturbances typically depends more on seed or rhizome sources, whereas surviving vegetation is more important in shaping forest development following lower severity disturbances. While stand development is normally slow, natural disturbances, such as insect outbreaks and windstorms, can greatly accelerate the creation of structural and compositional complexity at stand and landscape scales, especially in stands that are in early stages of development (*sensu* Oliver, 1980).

An accurate estimate of disturbance severity and of pre-disturbance structure is essential for projecting post-disturbance dynamics. For example, even high severity windstorms and beetle outbreaks normally preferentially kill canopy trees rather than understory individuals. Therefore, all other things being equal, post-wind or post-beetle regeneration is more rapid in stands with a higher density of advanced regeneration (also referred to as advance regeneration) and understory trees (i.e., stands in latter stages of development) at the time of the disturbance. Because disturbance history strongly affects stand structure, this example illustrates why disturbance history not only determines susceptibility to subsequent disturbances, but also post-disturbance regeneration. Importantly, although beetle outbreaks historically have primarily affected stands in latter stages of structural development, climate change has intensified outbreaks of bark beetles and weakened tree defenses, together resulting in younger stands in early stages of succession being severely affected by outbreaks (Kulakowski et al., 2012). One critical consequence of this novel phenomenon is that post-outbreak regeneration may become substantially slower than it has been over the past centuries because outbreaks are now occurring in stands without abundant advanced regeneration.

As disturbance severity increases, the role of pre-disturbance vegetation decreases, but does not disappear. Regeneration following even high-severity fires normally depends on seeds or rhizomes because such fires typically kill both canopy and sub-canopy individuals. In such cases, the effects of pre-fire vegetation on post-fire regeneration include variation in the dominance of trees that regenerate via resprouting or serotiny. However, it is important to note that even very high severity fires typically leave some survivors, which can then play a disproportionately large role in post-disturbance regeneration. Pre-fire structure also can shape post-fire substrate and heterogeneity of regeneration niches, with critical implications for post-disturbance forest development.

Post-disturbance regeneration following multiple disturbances in short succession is often quantitatively and qualitatively different from that following single disturbance events (Fig. 2). Understanding regeneration following such compounded disturbances is particularly important as disturbances become larger and more frequent under climate change, thus increasing the likelihood that a given forest is affected by multiple disturbances in short succession. Furthermore, compounded disturbances

Fig. 2 Regeneration following two or more disturbance is often slower than following a single disturbance. In some cases, such compounded disturbances can tip the ecosystem away from forest dominance toward an alternate stable state. Mount Zirkel Wilderness, Colorado. Photo: D. Kulakowski.

can exceed the resilience of some forests and lead to fundamentally different conditions, which may range from a shift in species composition (Gill et al., 2017; Johnstone et al., 2010; Kulakowski et al., 2013) to clear state change of non-forest vegetation (e.g., Buma and Wessman, 2011; Odion et al., 2010; Savage and Mast, 2005). The risk of such tipping points is especially high when post-disturbance climatic conditions are not favorable to the regeneration of native tree species.

Shifts in species composition following compounded disturbances in the Rocky Mountains have involved a change from dominance of conifers (that regenerate exclusively from seed) to dominance of angiosperms (specifically aspen (*Populus tremuloides*) that regenerate vegetatively). Interestingly, because aspen are less susceptible to most types of disturbance in the region, such a change in species composition may represent disturbance-mediated adaptation to climate change involving negative feedbacks that may reduce fire and other disturbances (Kulakowski et al., 2013). From the perspective of post-disturbance management, an additional difficulty stems from the fact that regeneration following compounded disturbances is more variable and less predictable than following individual disturbance. Thus, observed regeneration in the initial years following compounded disturbance can be a poor predictor of disturbance one or two decades later (Gill et al., 2017).

Compounded disturbances can occur for several distinct reasons—(1) similar underlying drivers of two or more disturbances increasing the frequency or extent of both disturbances, as with bark beetle outbreaks and fires (e.g., Mietkiewicz and Kulakowski, 2016); (2) an initial disturbance increasing the likelihood of a secondary disturbance, as with windstorms and insect outbreaks; or (3) a natural disturbance being followed by post-disturbance logging. Although tree cutting following disturbances is a common management response, from an ecological perspective, this practice can be considered a compounded disturbance that often magnifies the severity of the initial disturbance (Fig. 3). The increase in total disturbance severity is largely associated with intentional or accidental (e.g., caused by heavy machinery) mortality of individuals that survive the initial disturbance.

Managing Forest Disturbances

Appropriate forest management depends on ecological and social spatiotemporal context. The former refers to the particular requirements of species and ecosystems and the latter refers to social desires for the ecosystem in question (e.g., wilderness, timber production, etc.). Forests provide multiple ecosystem services, including those related to biodiversity, carbon, water, timber, protection from natural hazards, recreation, and spiritual values. Many of these services are mutually compatible and management can often promote multiple ecosystem services in the same forest. Although disturbances, especially large and severe ones, can be challenging from a management perspective, it is often possible to incorporate disturbances into management plans.

The ecological benefits of disturbances are well known (e.g., Stephens et al., 2013). Ecological disturbances can create spatial heterogeneity (e.g., variation in the amount and arrangement of surviving forest patches or trees) that can promote biodiversity, primary production, wildlife habitat, hydrogeologic protection, and ecosystem resilience (Johnstone et al., 2016; Seidl et al., 2014). Furthermore, variability of tree, stand, and landscape patch conditions can modulate disturbance size and severity and increase the likelihood of survival of individual or groups of trees (Buma and Wessman, 2011; Kulakowski et al., 2003; Kulakowski and Veblen, 2002) that subsequently can be important in post-disturbance regeneration. By contributing to forest resilience, spatial heterogeneity also facilitates ecological adaptation to future environmental change and helps sustain important ecosystem services (Turner, 2010). Consequently, a common goal of recent management is to increase structural diversity and other attributes of heterogeneity,

Fig. 3 Logging and associated road building following natural disturbances compounds and often intensifies the severity of the initial disturbance. Zakopane, Poland. Photo: D. Kulakowski.

in part as a safeguard for future conditions (Schütz, 2002). Post-disturbance logging often limits potential disturbance-created heterogeneity (Thorn et al., 2017) and reduces natural post-disturbance regeneration (Beghin et al., 2010).

Windthrow and insect outbreaks increase dead wood and light availability and, as a consequence, the abundance and diversity of many insect, plant, bird, and mammal species (Thorn et al., 2017). Disturbances can also introduce structural complexity in regions where long and intensive land use has homogenized landscapes and reduced the extent of structurally complex old-growth and structurally complex early-seral forests (DellaSala et al., 2017). Consequently, the role of natural disturbances in restoration has long been recognized in many different ecosystems (Noss et al., 2006; Turner et al., 2003). Restoration activities to create late seral conditions frequently involve felling and girdling trees to create snags—mimicking some of the effects of natural disturbances (Halme et al., 2013; Seibold et al., 2015). Selective post-disturbance logging (Priewasser et al., 2013) can maintain some ecologically important structural characteristics. However, soil compaction, soil nutrients, coarse woody debris, structural diversity, biological legacies, amount of surviving post-disturbance regeneration, and establishment of new post-disturbance regeneration are substantially different in most forests that have been clear-cut or logged following natural disturbance compared with forests that have been affected only by natural disturbance (Lindenmayer, 2009; Lindenmayer and Noss, 2006).

While disturbances often promote heterogeneity, if disturbances are too large, severe, or frequent, legacies of the pre-disturbance system may be lost and the ability of affected ecosystems to regenerate may be compromised (Kuuluvainen et al., 2017). This loss can shift ecosystems to alternate stable states, sometimes over extensive areas (Johnstone et al., 2016). Consequently, for management it is essential to understand the range of variability of disturbances that promote resilience, as well as identify the threshold beyond which disturbances may compromise it. Similarly, it is important to understand how resilience may be changing as a result of climate change (Seidl et al., 2017). Increased warming may intensify disturbance events, alter post-disturbance regeneration, and result in novel ecosystems including even non-forest alternate stable states. Tipping points are most likely to be crossed as a result of extreme climate events that increase the size, frequency, and intensity of disturbances (Allen et al., 2010), compounding events (Buma and Wessman, 2011), and post-disturbance climatic conditions that hinder post-disturbance regeneration (e.g., Harvey et al., 2016; Rigling et al., 2013).

Although disturbances have become larger, more frequent, or more severe because of recent changes in land use and climate (Seidl et al., 2011), in most cases, they do not, in and of themselves, threaten forest persistence (Kulakowski et al., 2017). Disturbances can, however, pose a risk to human populations and challenge forest management. For example, some ecosystem services such as timber production and natural hazard mitigation can be affected negatively by natural disturbances (Thorn et al., 2017; Vacchiano et al., 2014). Furthermore, potential risk to human populations associated with natural disturbances are intensified by urban expansion into forested areas as well as by forest expansion into urban areas. Consequently, in spite of advances in the fields of ecology and forestry, there is strong legal and social pressure to continue to suppress disturbances and control the natural dynamics of disturbed forests (Fares et al., 2015). This command-and-control approach to forest management

will become increasingly difficult to implement in the future as disturbances increase in size, frequency, and severity, which highlights the need for intensified conversations about how societies can coexist with disturbances.

Conclusions

Working with, rather than against, natural processes in managing forests is of paramount importance, especially in light of projected changes in climate (Moritz et al., 2014). Given the inevitability of disturbances in forest ecosystems and the ecological benefits of many disturbances, a key question is whether it is feasible to allow disturbances in some forests to operate as natural ecological processes and if so, how to optimize their ecological benefit while protecting human safety and well-being and maintaining other desired ecosystem services.

Approaches to forest management vary in intensity from passive management to intensive agro-forestry timber production (Duncker et al., 2012). Forest management needs to balance promoting natural processes while meeting societal needs for timber, fiber, and other raw materials (Kuuluvainen and Grenfell, 2012). Promoting natural processes requires an understanding of ecosystem variability in order to define acceptable limits of change. It is important to identify areas where letting natural processes shape forest ecosystems is compatible with other desired ecosystem services.

Disturbances are critical components of forest ecosystems. They cannot be considered in isolation, but rather as distinct and important stages in long-term forest health. By maintaining spatial heterogeneity in cover types, a range of successional stages, and a variety of biogeochemical states (stoichiometric ratios of nutrients and overall stocks) they foster biodiversity and resilience. Eliminating disturbances is neither possible, nor necessarily always desirable. Allowing disturbances, even large ones, to shape some forest ecosystems may promote ecological resilience in the face of climatic and environmental change. In some areas, containment of natural hazards may be of paramount social or economic importance (e.g., closest to homes and towns). However, disturbances can also provide important ecosystem services and can be compatible with multiple goals of forest use, even in densely settled and developed regions. Acceptance and appreciation of natural disturbances by the general public, especially in tightly couple human-natural systems, would facilitate (and may be necessary for) land managers and policy makers maintaining forests in more natural states.

Abstract

Tree plantations make up some 4% of the world's forests and are increasing as native forests are cut down to meet rising wood product demands. An additional 30% of the world's forests are in “production,” as defined by the Food and Agriculture Organization (FAO) of the United Nations. Compared to native (“real”) forests, plantations (“fake”) are often characterized by genetically modified tree genomes, over simplified forest structures (deficient in snags, down wood, large trees, and understory vegetation), single species monocultures, and greatly altered ecosystem processes (e.g., natural disturbances, hydrology, nutrient cycling, pollination, and food-web dynamics). Existing plantations can be managed to improve ecological integrity by enhancing structures otherwise absent in intensively managed systems. Conversion of native forests to plantations, however, needs to cease along with reducing wasteful consumption, increasing reliance on alternative wood fibers (e.g., hemp), recycling, and the use of engineered wood products that do not come from native forests.

What Exactly is a Forest?

Is a forest merely a collection of trees forming a canopy overstory (i.e., tree cover)? If we plant trees, does that make it a forest? How much of the Earth's forests is planted (more correctly termed “tree farms”)? How do planted forests differ from native forests? Can we meet wood demands while minimizing our ecological footprint?

To begin, when it comes to a forest, we each see what we want.

A forester sees a crop of trees to be extracted for timber-profit as soon as possible—the economic bottom line. An ecologist sees an ecosystem where the parts are interwoven and uniquely sculpted by natural processes; deforestation is antithetical to the sum-of-the parts.

When I take a hike into a native (unlogged) forest, I see a rich tapestry of life. This intimate dance of plant and animal, form and function, process and outcome is lacking in a plantation, especially plantations embedded in a sea of industrialized forestry. A walk in an industrial landscape has a different feel, smell, and much fewer dance partners. Wally Menne, a member of the Timberwatch coalition (<http://www.timberwatch.org.za>), aptly calls timber plantations “fake” forests (<http://wrm.org.uy/oldsite/countries/SouthAfrica/difference.html>). I adopt his terminology to distinguish real from fake, native from plantation, natural from engineered. In science, terminology matters—in this case, do we see forests as living, self-willed ecosystems or a crop to be manipulated for the bottom line?

How Are Forests and Plantations Defined and Counted?

To get at the root of the issue (literally), let's first explore some basic definitions.

Early Forest Definitions

The term “forest” has many origins (<https://en.wiktionary.org/wiki/forest>). From Latin—“foris” means outside and “forestis silva,” wood outside. Old French and Middle English terminology refer to forests as a wooded area kept for hunting. The Proto-Germanic

word is “furho” for fir-pine, and Proto-Indo European “perkus” means oak, to name a few. Ancient European cultures managed forests and woodlands as hunting grounds for royalty while also clearing woodlands for pasture and wood for building materials, heating, smelting, and leather production. Aboriginal peoples applied spiritual connection to forests (e.g., see <http://www.native-languages.org/legends-forest.htm>). In sum, forests and woodlands have been in cultivation for thousands of years, ultimately leading to widespread deforestation (Williams, 2003) and contributing to the collapse of early civilizations (Diamond, 2005). Deforestation and forest degradation is rapidly consuming the world’s native forests (Williams, 2003; Mackey et al., 2014).

Common Forest Definitions

According to Merriam, a forest is “a usually large group of plants and especially trees under cultivation.” The Food and Agricultural Organization (FAO, 2010) of the United Nations defines forest as “a land area of greater than 0.5 ha, with a tree canopy cover of greater than 10%, which is not primarily under agricultural or other specific nonforest land use. In the case of young forests or regions where tree growth is climatically suppressed, the trees should be capable of reaching a height of 5 m in situ, and of meeting the canopy cover requirement” (<https://www.cbd.int/forest/definitions.shtml>). However, FAO’s definition is based on minimum forest cover only (quantity) and lacks attention to forest quality.

Ecological Forest Definitions

Most standard text books of forest ecology (e.g., Perry et al., 2009) define forests as a community of interacting species organized by structural elements and species composition that perform specific functions. Structure refers to the physical aspects of a forest, such as the overstory canopy. Notably, from a structural standpoint, trees can be alive or dead and standing or down. Some forests, such as mature (>80 years) Douglas-fir (*Pseudotsuga menziesii*)/western hemlock (*Tsuga heterophylla*) in the Pacific Northwest are comprised of a continuous, multilayered canopy from the ground up—shrubs, lower, mid, and overstory strata. Composition refers to the actors, the characteristic species and genomes. Functions are the inner workings of a forest that orchestrate processes like photosynthesis, nutrient cycling, carbon sequestration (photosynthesis), disturbance dynamics, and food-web interactions. A native forest has all the parts working together—structure (all age classes especially older), composition (the natives), and function (e.g., natural disturbances, food-web dynamics). It should be noted that a forest is not just a collection of plants. The animals codesign the fundamental elements. For instance, the waste pellets of flying squirrels (*Glaucomys sabrinus*) are packed with fungal spores that inoculate top soil with mycorrhizae fungi that then form underground networks that aid plants in uptake of water, minerals, and vital nutrients (a sort of *Avatar* communication subhighway). Invertebrates aid in decomposition and nutrient cycling. Bats, birds, and insects disperse seeds and pollinate flowers. In turn, these codependent relations determine the structural elements of the forest community (Maser, 1994). When we tinker (or engineer) with the parts in forestry operations, we lose most of the key structural elements, which in turn affects forest relations and functions.

Common Plantation Definitions

Wikipedia defines a plantation as a large-scale farm that specializes in cash crops. In particular, tree plantations (tree farms) have an explicit purpose—high-yield production of wood fiber in the shortest time. This often includes one or two commercially valuable or crop species (e.g., Douglas-fir, *Pinus*, *Eucalyptus*, *Poplar*, *Picea* spp.) (Fig. 1A and B). Tree seedlings are grown in tree “nurseries,”

Fig. 1 (A) Douglas-fir timber plantation (foreground) on US Department of Interior Bureau of Land Management lands in western Oregon showing extensive clear-cuts and plantations (background) within an industrial landscape matrix. (B) Old-growth Douglas-fir/hemlock stand showing vertical (tree-size class variability, snags) and horizontal (shrubs, forbs) complexity. Canopy gaps created by tree fall from natural causes provide diverse successional stages within the forest stand that are not present in plantations. Photo: D. DellaSala.

sometimes genetically manipulated for certain growth features (straight stem, rapid wood accumulation) and resistance to disease. Seedlings are planted in tight rows to maximize yield. In some places (e.g., southeast Alaska), tree planting is not necessary because a natural seed source is available and ideal growing conditions are sufficient without propagation. In other regions (e.g., Indonesia), tree regeneration is not even attempted leading to deforestation and widespread conversion (e.g., palm oil or slash and burn agriculture of the tropics).

The Forest Stewardship Council (FSC) (n.d.) defines plantations as:

forest areas lacking most of the principal characteristics and key elements of native ecosystems as defined by FSC-approved national and regional standards of forest stewardship, which result from the human activities of either planting, sowing or intensive silvicultural treatments (source: FSC-STD-01-001).

FSC Explicitly States That Plantations Include

the use of establishment or subsequent management practices in planted forest stands that perpetuate the stand-level absence of most principle characteristics and key elements of native forest ecosystems will result in a stand being classified as a plantation. ... Except for highly extenuating circumstances the following are classified as plantations: cultivation of exotic species or recognized exotic sub-species; block plantings of cloned trees resulting in a major reduction of within-stand genetic diversity compared to what would be found in a natural stand of the same species; cultivation of any tree species in areas that were naturally non-forested ecosystems.

Site Preparation

Preparing a site for a plantation often involves the use of herbicides to reduce tree competition with shrubs and other noncommercially valuable species. Plantation management can include fertilizers and pesticides to enhance tree growth and reduce tree mortality. After the dense tree canopy closes (1–2 decades depending on site factors—i.e., “pole” stage), this is often followed by precommercial thinning (although some commercial value is possible as pulp or woody biomass) to reduce competition among tree stems. Decades later a commercial thin can be performed to further reduce competition and extract economic value. Once past the point of maximum growth (referred to as cumulative mean annual increment), trees are then logged again to maximize profit and jumpstart the commercial process (note: some landowners may skip the culmination phase and harvest trees even sooner). Fast growing trees on short logging rotations replace the diversity of natural successional stages with fake forests kept in a perpetual stage of young growth, clearcut harvest, and regrowth.

Planted Forest

According to FAO (2010), forest plantations are a subset of planted forests consisting primarily of introduced species that make up nearly 4% of total forest area, or 140 million hectares globally. Productive forest plantations, primarily established for wood and fiber, account for 78% of forest plantations, and “protective” forest plantations, primarily established for conservation of soil and water, 22%. The area of forest plantations increased by about 2.8 million hectares annually from 2000 to 2005, 87% of which is productive forest plantation. Additionally, while not plantations per se, FAO (2015) reports 1.2 billion (30%) of ~4 billion hectares of forests world-wide are in “production” (Fig. 2). As noted, FAO defines a forest as having tree cover >10%.

Carle and Holmgren (2008) define “planted forests” as: (1) forests of native species established through planting, seeding, or coppice of planted trees; (2) forests of introduced species, and in some cases native species, established through planting or seeding mainly for production of wood or nonwood goals; and (3) forest of native or introduced species established through planting or seeding mainly for provision of services. They provide an overall estimate of planted forests summed for all three categories and projected forward under different management scenarios (Fig. 3). For instance, planted forest projections show the current global

Fig. 2 The world's forests by management category (FAO, 2010).

Fig. 3 Area of planted forests ($\times 10^6$ ha) in 2005 (blue) vs. two projected scenarios for 2030 (from Carle and Holmgren, 2008). Scenario 1 (orange) assumes no increase in productivity and the current expansion of planted forests slows down. Scenario 2 (gray, combined scenarios 2 and 3 of Carle and Holmgren, 2008) assumes planted area continues at the current rate and/or increases as a result of genetic modifications and technological improvements.

increase may continue at least until 2030, particularly in Asia (e.g., palm oil production). It can be assumed that, as planted forests increase, so too will deforestation of native forests.

How Do Real vs. Fake Forests Differ Ecologically?

While this article focuses on comparing plantations to native forests, other forest manipulations, such as “seminatural” and “modified natural,” deserve recognition given their global prominence. For instance, Carle and Holmgren (2008) define modified natural as forest naturally regenerated with native species where there are visible signs of human activity. Additionally, seminatural is considered a forest where silvicultural practices are in place for intensive management (e.g., selective or high-grade logging). Thus, the level of human intervention can be illustrated along an ecological integrity gradient from highest (native) to lowest (plantation; Fig. 4). Integrity refers to native species, functions, and processes expected for a specific ecosystem type based on historic or reference conditions.

Regional and site-specific factors need to be considered in any comparison of fake vs. real forests; however, some general patterns emerge (Table 1). Real forests are much more complex at all levels of biological organization: genetic (genomes are highly variable compared to nursery “stock”), native species richness, and ecosystem processes—the latter both above and below ground. In this case, the sum-of-the-ecosystem parts is greater than the whole while plantations sum to much less than the whole.

Can Plantations Be Managed (Restored/Enhanced) for Ecological Integrity?

The first principle of restoration is to stop the loss (hemorrhaging) of integrity before it even happens—that is—conversion of real to fake. However, for plantations already in production and lacking key elements, restorative actions can make plantations as “seminatural” as possible by planting with diverse native seeds and enhancing structures present on site. For instance, forest thinning (e.g., precommercial) in a dense stand of young trees (thicket or “dog-hair” stands) can enhance structural diversity by opening forest canopies to increased sunlight that stimulates understory development (Fig. 5A and B). Girdling (killing) trees for snag creation provides nesting, foraging, and dens sites for wildlife, while felling trees and leaving them on site provides downed logs (along with moist microclimates and nutrient cycling) for amphibians, invertebrates, and aquatic species when logs fall into streams. Horizontal diversity also can be enhanced via stops and gaps in thinning (i.e., unthinned trees alternating with created openings). While restoration can improve integrity at the site level, the net effect at the landscape scale is small especially given chronic impacts (e.g., to aquatics) from an extensive road network needed to access plantations (Fig. 6).

Fig. 4 Hypothetical integrity (native species, structure, function/processes) gradient based on degree of alteration of composition, structure, and function. Graphics created by Freepik, modified by Christina Mills.

Table 1 Generalized characteristics and differences between “real” vs. “fake” forests

Characteristic	Real Forest	Fake Forest
Genetic diversity	Highly varied and adaptive/ resilient to climate change	Greatly simplified and low resilience to climate change
Tree and other plant species richness	Medium-exceptional depending on site factors and forest type (tropical, temperate, boreal)	Low, monoculture
Animal richness	Medium-high-extraordinary (e.g., tropics)	Low
Apex predators	Important habitat	Highly degraded and typically absent
Imperiled species	Important/critical habitat	Highly degraded and typically absent
Soils and below-ground processes	Productive, well-developed soil horizons, soil biota (e.g., decomposers, mycorrhizae, native seed sources), abiotic processes (nutrient cycling, decomposition) (although soil nutrients deficient in tropical rainforests and forests on ultramafic substrates)	Often damaged, depleted and requiring fertilization
Snags and down wood	Abundant with diverse size and decay classes	Scarce/rare
Structural diversity (vertical, horizontal complexity)	Generally abundant depending on site factors, forest types, age classes	Little to none
Forest age classes	Full successional gradient often present at site or landscape scale, especially rare types such as structurally complex young and old growth stages	Even aged
Climatic refugia (e.g., relatively cool, moist microclimates)	Present and functional	Highly altered or absent
Hydrological cycle	Intact	Dysfunctional especially in areas of high road densities
Carbon sequestration and storage	Medium-high-extraordinary depending on site and forest type (carbon sink)	Sequestration but very low carbon stores and limited carbon retention (carbon source initially)
Natural disturbances	Functional (e.g., fires, floods, insects) with many resistant and resilient forest properties	Highly altered with low levels of resilience/resistance often amplifying or compounding natural disturbances (e.g., more intense forest fires due to dense planting of small trees that act as tinder)
Societal benefits	Myriad ecosystem services (multi-functional) but often de-valued (clean air, clean water, recreation)	Economics predominate decision making (one dimensional)
Invasive species, diseases, insect outbreaks	Absent or in low numbers with high levels of resistance	Present or in high numbers with little resistance
Intactness/connectivity (landscape scale)	Corridors, elevation and latitudinal gradients	Highly fragmented especially when combined with roads and industrial-scale logging
Deforestation/degradation pressure	High-extreme pressures across all forest biomes	Highly degraded and likely not being used to relieve pressure to native forests
Integrity (sum of native species composition, function, process)	High to exceptional	very low (see Figs. 2, 3)

Relative differences depend on regional and local site factors, forest types, and management intensity.

Fig. 5 (A) Dense “dog-hair” stand of Douglas-fir that was planted on an industrial landscape after clearcutting coast redwood (*Sequoia sempervirens*) in northern California. (B) Redwood National Park thinning of young Douglas-fir to increase growing space for restoring previously logged redwood stands, the native forest type in this region. Note light penetrance in thinned area. Photo: D. DellaSala.

Fig. 6 Deforestation and roads in Borneo. No amount of restoration can recover this landscape destroyed from cumulative (chronic) effects of industrial logging rampant in Malaysia. Photo: D. DellaSala.

Notably, the FSC has developed 10 principles and related criteria and indicators for forest certification to address ecological, social, and economic interests in forest management. Principle 10, in particular, is specific to plantations ([Appendix 1](#)). FSC assumes plantations managed this way provide necessary wood fiber while reducing pressures to native forests that otherwise would not need to be logged. While this is important in principle and should be encouraged, it is not occurring at a scale sufficient to reduce deforestation globally.

Conclusions

Plantations are fake forests because they lack the integrity of real forests. Fake forests are expanding globally, at the expense of real forests. Notably, it is often claimed that tree plantations have an indirect conservation benefit in reducing pressures to native forests as in the case of New Zealand, where native forest logging has ceased and logging is restricted to existing plantations. However, this is the exception rather than the rule. Nonetheless, *Sedjo and Botkin (1997)* estimated that, in order to meet global demand for wood products, some 5% of the world forests would need to be maintained in plantations. We are nearly at the 5% level, as plantations continue to increase globally along with rising population and consumption levels. Plantation and planted forests are projected to increase or slow down through 2030, resulting in even more deforestation, unless remaining native forests are conserved. Reduction in wasteful consumption, use of alternative wood fibers (e.g., hemp), recycling, and engineered wood products can all play an increasing role in reducing pressures to the world’s native forests. In the meantime, existing plantations can be managed to limit their ecological footprint by enhancing structures, planting with native seed sources, and FSC certification or equivalent management. Moreover, real forests are grossly under-valued for myriad ecosystem benefits and biodiversity values that they provide to society, as pressures to log them continue to mount.

Appendix 1 FSC Principle 10 for Plantation Management (Note: more specific regional guidance, intent, and application is provided by FSC but not included here for simplicity)

Plantations shall be planned and managed in accordance with Principles and Criteria 1–9, and Principle 10 and its Criteria. While plantations can provide an array of social and economic benefits, and can contribute to satisfying the world’s needs for forest products, they should complement the management of, reduce pressures on, and promote the restoration and conservation of natural forests.

C10.1 The management objectives of the plantation, including natural forest conservation and restoration objectives, shall be explicitly stated in the management plan, and clearly demonstrated in the implementation of the plan.

- Indicator 10.1.a Consistent with all the indicators within Principle 10 and requirements of Principle 7, the management plan contains clear descriptions of the management goals and prescriptions for plantations on the FMU (forest management unit), of the rationale for plantation management within the FMU, and the relationship between the plantations and natural forest conservation and restoration objectives within the unit.
- Indicator 10.1.b The forest owner or manager demonstrates clear progress in implementation of the components of the management plan addressing natural forest conservation and restoration objectives as they pertain to plantation management.

C10.2 The design and layout of plantations should promote the protection, restoration and conservation of natural forests, and not increase pressures on natural forests. Wildlife corridors, streamside zones and a mosaic of stands of different ages and rotation periods shall be used in the layout of the plantation, consistent with the scale of the operation. The scale and layout of plantation blocks shall be consistent with the patterns of forest stands found within the natural landscape.

- Indicator 10.2.a For plantations established on soils capable of supporting natural forests, harvest units shall be arranged to provide or maintain areas of vegetative cover that allows populations of mid to late successional and sedentary native plant and animal species to survive or be reestablished within the plantation.
- Indicator 10.2.b New plantation establishment does not replace, endanger, or otherwise diminish the ecological integrity of any existing natural ecosystems on the FMU, including primary, natural, or seminatural forests on the FMU. Note that restoration plantations may be established on degraded forests.
- Indicator 10.2.c In all regions except the Pacific Coast, openings lacking within-stand retention are limited to a 40-acre average and an 80 acre maximum. Harvest openings larger than 80 acres must have retention as required in Indicator 10.2.d and be justified by credible scientific analysis. The average for all openings (with and without retention) does not exceed 100 acres. Departures from these limits for restoration purposes are permissible but also must be justified by credible scientific analysis.
- Indicator 10.2.d On openings larger than 80 acres that are justified by credible scientific analysis, live trees and native vegetation are retained in a proportion and configuration that are consistent with the characteristic natural disturbance regime in each community type, unless retention at a lower level is necessary for restoration purposes.
- Indicator 10.2.e In all regions except the Southeast, before an area is harvested, regeneration in adjacent forested areas (either natural forest or plantation) on the FMU must be of the subsequent advanced successional habitat stage, or exceed 10 ft in height, or achieve canopy closure along at least 50% of its perimeter.

C10.3 Diversity in the composition of plantations is preferred, so as to enhance economic, ecological and social stability. Such diversity may include the size and spatial distribution of management units within the landscape, number and genetic composition of species, age classes and structures.

- Indicator 10.3.a Plantation management alone or in combination with natural forest management contributes to the economic stability of the local community, or helps the owner maintain the property as a working forest.

- Indicator 10.3.b On plantations established on soils capable of supporting natural forests, the forest owner or manager maintains, conserves, and/or restores forest health and diversity, including wildlife habitat and soil productivity, by maintaining appropriate diversity of size, structures, age classes, species and genetics across the plantation FMU.

C10.4 The selection of species for planting shall be based on their overall suitability for the site and their appropriateness to the management objectives. In order to enhance the conservation of biological diversity, native species are preferred over exotic species in the establishment of plantations and the restoration of degraded ecosystems. Exotic species, which shall be used only when their performance is greater than that of native species, shall be carefully monitored to detect unusual mortality, disease, or insect outbreaks and adverse ecological impacts

- Indicator 10.4.a Species shall be used for planting that are suitable and appropriate to the site and are consistent with maintaining FMU health and productivity. Species native to the region are preferred to other species (not native to the region).
- Indicator 10.4.b For the Northeast, Ouachita/Ozark, Rocky Mountain, Southwest, Pacific Coast and Lake States regions, the use of exotic species (i.e., species not native to the region) is contingent on credible scientific analysis confirming that the species in question is non-invasive, will not create significant risk to forest health, and performs better than species native to the region. If exotic plants are used, their provenance and the location of their use are documented and their ecological effects are monitored.

C10.5 A proportion of the overall forest management area, appropriate to the scale of the plantation and to be determined in regional standards, shall be managed so as to restore the site to a natural forest cover.

- Indicator 10.5.a Areas of forest and/or plantation to be restored to natural conditions are chosen through a landscape analysis that focuses on enhancing principle characteristics of the native ecosystem or providing important ecological benefits at the stand or landscape level.
- Indicator 10.5.b Areas to be restored to natural conditions are prioritized where the analysis indicates the greatest conservation gain and are designed for long-term restoration.
- Indicator 10.5.c Management plans should clearly state the extent and location of areas selected for such restoration, as well as the rationale for their selection.
- Indicator 10.5.d Areas of forest and/or plantation to be restored or maintained as natural forests are managed to provide a diversity of community types, wildlife habitats, and ecological functions native to the site.
- Indicator 10.5.e The ratio and spatial distribution of plantations, with respect to natural and seminatural forests, maintains and/or restores the landscape diversity of community types, wildlife habitats, and ecological functions similar to a mosaic of natural forests.
- Indicator 10.5.f Where natural ecosystems were previously converted to plantations, a percentage of the total area of the FMU must be maintained and/or restored to natural or seminatural cover. The minimum percentage area that is maintained and/or restored in natural or seminatural state is:
 - For 100 acres or less, at least 10%.
 - For 101–1000 acres, at least 15%.
 - For 1001–10,000 acres, at least 20%.
 - For >10,000 acres, at least 25%
- Indicator 10.5.g All plantations on forest soils on public lands are managed to restore and maintain natural forest vegetation, structure, function, and habitats, and fully meet, at the earliest possible time, all aspects of Principles and Criteria 1–9 that are relevant to natural forests for the area.

C10.6 Measures shall be taken to maintain or improve soil structure, fertility, and biological activity. The techniques and rate of harvesting, road and trail construction and maintenance, and the choice of species shall not result in long term soil degradation or adverse impacts on water quality, quantity or substantial deviation from stream course drainage patterns.

- Indicator 10.6.a Forest operations do not result in long-term adverse impacts to soil productivity, water resources, and hydrology. Soil disturbance is minimized during road/trail work and site preparation, and site preparation is done in accordance with BMPs.
- Indicator 10.6.b Tree seedlings are planted in a way that minimizes damage to the soil, while facilitating seedling survival. Tree seedling species are selected appropriate for maintaining long-term site productivity.
- Indicator 10.6.c Thinning is implemented in a manner that minimizes site disturbance and damage to the residual stand of crop trees and other desired vegetation (See Criterion 6.5).
- Indicator 10.6.d Fertilizer is applied only when all the following conditions are met:
 - Soil classification or foliar analysis indicates one or more nutrients are a limiting factor for forest productivity. Data and/or scientific literature suggest that the response to fertilization is economically justified. Where necessary due to topography, soils, or other conditions, measures are taken to prevent damage from fertilizer runoff or leaching. This includes preventing influences on native low-nutrient ecological systems, such as pitcher plant bogs, or on ground and surface water quality. Fertilizer application maintains or enhances soil condition and site productivity.
- Indicator 10.6.e Sufficient woody debris and other organic matter is retained within plantation stands to ensure adequate soil structure and nutrient recycling.

C10.7 Measures shall be taken to prevent and minimize outbreaks of pests, diseases, fire and invasive plant introductions. Integrated pest management shall form an essential part of the management plan, with primary reliance on prevention and biological control methods rather than chemical pesticides and fertilizers. Plantation management should make every effort to move away from chemical pesticides and fertilizers, including their use in nurseries. The use of chemicals is also covered in Criteria 6.6 and 6.7.

- Indicator 10.7.b A strategy is in place to control fire damage. Where applicable, prescribed burns are conducted according to BMPs and with adequate planning, equipment, training and weather conditions to maintain control of the burn within the burn plan area.
- Indicator 10.7.c The forest owner implements a strategy to prevent or control invasive species, as noted in Indicator 6.3.h

C10.8 Appropriate to the scale and diversity of the operation, monitoring of plantations shall include regular assessment of potential on-site and off-site ecological and social impacts, (e.g. natural regeneration, effects on water resources and soil fertility, and impacts on local welfare and social well-being), in addition to those elements addressed in Principles 8, 6 and 4. No species should be planted on a large scale until local trials and/or experience have shown that they are ecologically well-adapted to the site, are not invasive, and do not have significant negative ecological impacts on other ecosystems. Special attention will be paid to social issues of land acquisition for plantations, especially the protection of local rights of ownership, use or access.

- Indicator 10.8.a Monitoring of the impacts of plantations, both on and off-site, is conducted in the same manner as the monitoring of natural forests, in accordance with Principles 4, 6, and 8.

C10.9 Plantations established in areas converted from natural forests after November 1994 normally shall not qualify for certification. Certification may be allowed in circumstances where sufficient evidence is submitted to the certification body that the manager/owner is not responsible directly or indirectly of such conversion.

- Indicator 10.9.a For plantations established in areas converted after 1994, the forest owner or manager demonstrates to the CB that the manager/owner was not directly or indirectly responsible for the conversion of the natural forest to the plantation.
- Indicator 10.9.b For plantations established in areas converted after 1994, the forest owner or manager develops and implements a plan to restore the plantation stands to conditions characteristic of natural forests and to manage those stands in compliance with all Indicators of Principles 1–9 as quickly as feasible.

Abstract

The Neotropical rainforests combine to form the largest expanses of rainforest on the planet. Holding the highest levels of biodiversity on earth, the Neotropical rainforests range from southern Mexico and the Caribbean to Brazil and Bolivia. Found below 500 m elevation, lowland rainforests are characterized by a tall canopy with emergent trees extending above it and multiple layers of vegetation below. The isolated evolution of floras and faunas in North and South America and the eventual connection of the two continents led to the great “American Interchange” of species, contributing to the high diversity of both. Although they can be broken down into four regions (Amazon, Atlantic/Paraná, Chocóan, and Mesoamerican/Caribbean), when combined the rainforests of the Neotropics are greater in extent than any other rainforest ecosystems. Serious threats to the Neotropical rainforest come from agricultural frontiers driven by both cattle ranching and crop agriculture and resulting in clearing of large expanses of forest. Forest loss is exacerbated by and contributes to climate change, with increases in drought, forest fire, and hurricane severity all further imperiling the forests. However, there are positive advances in conservation of the Neotropical rainforests, with some countries leading the way and increased grassroots and indigenous engagement leading to a promise of better protection of the monumentally important rainforests of the Neotropics.

Introduction

Hyperdiverse, expansive, and increasingly threatened, the Neotropical rainforests are both the terrifying jungles that struck fear into early European explorers and the biological wonders that amaze scientists today. Since long before European intervention, they have been both the irreplaceable context to local cultural traditions and crucial to global climate function. Neotropical rainforests are found in the Americas, ranging from southern Mexico and the Caribbean Islands south to Bolivia (Fig. 1). Their geography in the “New World” (Neo, from Greek *neos* means new) is not the only aspect that distinguishes them from the other rainforests of the world. They contain a large proportion of the earth’s biodiversity, including holding the most species-rich locations on the planet, on the eastern slope of the Andes mountains. Although the Amazon basin rainforests are the best known of the Neotropical rainforests, there are several other distinct regions, including the Mesoamerican and Caribbean rainforest, the Chocóan rainforest of Colombia, Panama and Ecuador, and the Atlantic and Paraná rainforest of coastal Brazil (Fig. 1).

Tropical rainforests are defined biogeoclimatically by receiving at least 2000 mm of rainfall each year and occurring between 23° 27' N latitude and 23° 27' S latitude. Lowland rainforests, below 500 m elevation comprise the largest extent of Neotropical rainforests. Between 500 and 1700 m, premontane rainforests are found, and montane cloud forests occur from around 1200 and 1700 m. Species do not recognize these divisions but have their own habitat limitations, thus lowland, premontane, and montane forests share some species as well as having their own unique assemblages. The focus of this entry will be on Neotropical *lowland* rainforests.

Rainforests are characterized by different layers of vegetation: understory, mid-level, canopy, and emergent. In the Neotropics, canopy height is typically 30–50 m, but giant trees called “emergents” rise above the canopy and reach well over 50 m tall (Fig. 2). Like other tropical rainforests, herbaceous vines and woody vines called “lianas” are ubiquitous, with larger lianas indicating a relatively undisturbed forest. The understory is filled with tree saplings along with a diverse community of woody and herbaceous monocots, with high species richness in the families Arecaceae (palms) and Heliconiaceae (heliconias). The lowest layers receive relatively little light and growth of tree seedlings and saplings in closed canopy conditions is very slow. Treefall gaps and the pioneer species that take advantage of them play an important role in maintaining diversity of Neotropical rainforests. The complex, layered structure of the forest plant communities allows for a multitude of niches for animals to occupy, one of the key reasons that rainforest faunas are the most diverse on the planet.

Fig. 1 Lowland rainforest regions of the Neotropics, indicating the extent of where rainforests occurred historically. Figure prepared by Joel T. Betts using Ecoregions 2017 shapefiles for forest delimitation (Dinerstein et al., 2017) and ESRI, USGS, and NOAA basemaps.

Fig. 2 Rainforest canopy in southeastern Nicaragua still undergoing regeneration 20 years after hurricane impact. Photo by G. R. Urquhart.

Rainforests of the Americas have the most tree species at low densities (<2 stems >10 cm dbh per hectare) of any ecosystem in the world. There is high plant diversity at the local scale (alpha diversity) and high diversity between sites (beta diversity). Overall there are an estimated 50,000 plant species in the Amazon Basin alone (Hubbell et al., 2008). A single hectare of Amazonian rainforest may contain over 300 tree species and 900 vascular plant species (Balslev et al., 1998). A 50-ha plot on Panama's Barro

Colorado Island has over 650 woody species, with over 500 species of trees over 10 cm diameter at breast height (Condit et al., 2005). Even though high diversity and low species density are the norms for lowland Neotropical rainforests, some forests are noted for having a single species overrepresented. The Sarapiquí region of Costa Rica, where La Selva Biological Station is located, is known for its high densities of *Pentaclethra macroloba*, yet still maintains high overall beta diversity.

Biogeographical Distribution

Lowland rainforests are distributed across the Neotropics where sufficient rainfall occurs. Larger Caribbean islands with consistent rainfall have rainforest, with large expanses found on Puerto Rico, Hispaniola, Cuba, Jamaica, and Trinidad and Tobago. The Caribbean Coasts of Mexico, Central America, and northern South America have extensive rainforests, and the Atlantic coast of Brazil is home to unique Atlantic rainforest. Along the Pacific Coast of Central America some rainforest occurs, but due to prevailing winds and orographic lifting, much of the Pacific side of Central America is tropical dry forest. The Darién of Panama and the Pacific lowlands of Colombia and Ecuador are home to the distinct Chocó rainforest ecoregion. Finally, the Amazon watershed from the foothills of the Andes to the mouth of the mighty river is extensively covered in rainforest, with several unique ecoregions making up the largest tropical rainforest on earth.

Prevailing “easterly” winds in the Neotropics blow primarily from east to west, with slight variation as northeasterly or southeasterly based on the position relative to the Intertropical Convergence Zone (ICTZ). To the north of the seasonally-shifting ICTZ, winds blow from northeast to southwest, and to the south they blow from southeast to northwest. The typically northeasterly winds of Central America thus make landfall on the Caribbean Coast carrying moisture absorbed over the sea, depositing rain as they move inward. Mountain ranges that cause uplift of moist air are further responsible for rainfall patterns, leading to heavy rainfall on the eastern side of Central American mountain ranges.

The lowland rainforests of North and South America have many distinct forms. In areas where flooding is not a regular occurrence, “terra firme” forests grow. While there is no typical terra firme forest that characterizes the Neotropics, there are shared characteristics. Terra firme forests are dominated by broad-leaved evergreen trees that often reach incredible size. Trees typically have smooth trunks and buttressed roots. Tree limbs are in the upper third of the tree where they can access sunlight that reaches the canopy. Terra firme forests often have very poor soil quality, with heavy clays and little topsoil. Leaf litter decays almost as soon as it reaches the forest floor, creating a rapid nutrient cycle with little accumulation of nutrients in the soil. The overall root system is shallow because both nutrients and water are most available near the surface. Terra firme forests have very high alpha (local) and beta (regional) diversity.

Seasonal flooding produces different types of rainforests. Along the Amazon, two types of “flooded forest” exist: Igapó and Varzea. Floodplain forests like these comprise about 4% of the Amazon basin. The Igapó forest is found along blackwater rivers and flooding extends high into the Igapó during parts of the year. The Varzea is associated with “whitewater” rivers, those in the Amazon that carry high sediment load. In both types, fish enter the forest itself during flooding, and many fish species are involved in fruit consumption and seed dispersal. The large Pacu, a type of tetra and best known of the seed-eating fish, has the ability to crush large seeds with strong teeth and throat plates. The other major drainage of tropical South America, the Orinoco River system, has similar types of flooded forests.

In Central America, the Colombian Chocó, and the Amazon Delta, seasonally inundated forests are often dominated by the large palm, *Raphia taedigera*. This sole native representative of a largely African genus has leaves reaching 18 m in length, and was once thought introduced by European trade. Neotropical palm swamps are not only formed by *Raphia*, but *Mauritia flexuosa* also forms large monodominant stands along tributaries of the Amazon and Orinoco rivers.

Historical Biogeography: Creation and Isolation of the Neotropics

Africa and South America were once merged as a massive land form called West Gondwana, a subsection that broke off of the larger Gondwanaland supercontinent. Before West Gondwana split, a large contiguous rainforest spread over much of the megacontinent. The split of Africa and South America occurred around 110 million years ago (mya), before many of the modern families of plants and animals emerged. Thus, groups like the “New World Monkeys” evolved after the split of West Gondwana, in isolation from their counterparts in the Old World.

South America was an isolated continent for approximately the next 100 million years. North America and South America existed in isolation from each other until around 2.8 mya when the Central American isthmus closed the gap in western Panama (O’Dea et al., 2016). Thus, distinct floras and faunas evolved in the two regions and the great “American Interchange” occurred when the isthmus formed a land bridge. Locations in southern Central America, like Costa Rica and Panama, show a high proportion of species from both continents.

Groups that evolved in South America include the cavimorph rodents (pacas, guinea pigs, capybaras), the New World monkeys with their prehensile tails, smaller cats in the genus *Leopardus*, and the *Heliconia* herbs. North America produced the even-toed ungulates like peccaries and deer and the large cat species. Once the land bridge was completed, these spread into the new continent. Although 2.8 million years have passed since they spread northward, cavimorph rodents have not extended outside of the Mesoamerican tropical forests into North America’s other ecosystems. Conversely, an amazingly adaptable large cat, the puma

(*Puma concolor*), colonized the rainforests of South America and eventually extended as far south as the temperate biomes of Tierra del Fuego.

Biodiversity

Species richness in the Neotropical rainforest can be higher than any other location on earth, with eastern Ecuador, Peru, and Colombia having the highest local biodiversity. Colombia is home to ~18% (>1800 species) of the earth's bird species with only 0.02% of the earth's land surface. Ecuador is home to ~15% of the bird species in an even smaller land area. Although Colombia and Ecuador are home to a wide variety of ecosystems, which explains some of the diversity, the lowland rainforest bird diversity is particularly high, in part because both Colombia and Ecuador are home to lowland rainforests in the Amazon and the Chocó regions, each of which has unique taxa and many related but distinct species.

Insect diversity is extremely high in the Neotropical rainforests. Erwin (1982) found 955 beetle species on a single tree species (*Luehea seemanni*) in Panama. From this extreme diversity, he recalculated the upper bound for how many species of arthropod may exist on earth, and other scientists extended his estimates to claim that there may be 50 million species on the planet. The key to Erwin's and other arguments lies in the extreme diversity of trees in the tropical rainforest and the host-specificity of many insects.

Many hypotheses exist for the high species richness in the tropics (Chazdon and Whitmore, 2002), but none singularly can explain the immense biodiversity of the Neotropical rainforest. Three major factors contribute to high species richness in the Neotropics: (1) the immense geographical extent of the Neotropical rainforest, especially the contiguous Amazon basin; (2) the floral and faunal exchange between the North American and South American biotas; and (3) the Andes and other mountains and elevational gradients.

Neotropical rainforests extend over a greater geographical area than any other tropical rainforest region. The Amazon basin holds over 60% of the world's remaining tropical forests (Laurance et al., 2005) and an estimated 50,000 plant species (Hubbell et al., 2008). The 5.3 million square kilometers of closed canopy forest in the Amazon is equivalent to the size of western Europe, constituting the single largest rainforest on earth. The small geographic ranges of many species in the Neotropics mean that over the great extent of the Amazon, several similar but unique species are encountered.

The floral and faunal interchange that took place after the completion of the isthmian land bridge in Panama strongly contributes to the biodiversity of Neotropical rainforests. South American species migrated northward and North American species spread into the southern continent. This mixing of already diverse floras and faunas contributes to the incredibly high diversity found in northern South America.

Elevational gradients are well known to increase diversity because species specialized for certain elevations will overlap at transitional elevations. The mountain ranges that form the sierras of Central America and the Andes of western South America create elevational gradients that lead to specialization. It is no surprise that the most diverse regions on earth are the foothills of the Andes in eastern Ecuador and Peru.

Important Species and Biological Groups

Neotropical rainforests are home to thousands of notable and unique species. Stunning flowers, colorful butterflies, charismatic mammals, and countless other organisms all contribute to the splendor of the rainforest (Fig. 3). To highlight some of the more notable groups and species, examples from different taxa are described below. Those selected below serve only to highlight some of the unique groups and are in no way intended to say that those chosen are more important than other organisms.

Fungus: *Vesicular arbuscular mycorrhizae* (VAM): Mycorrhizal fungi live in association with plant roots and provide a vast underground network of hyphae allowing the movement of nutrients necessary to support the tree growth of the forest. Although ectomycorrhizae that ensheath the tree roots are most prevalent in the Dipterocarp rainforests of southeast Asia, the rainforests of the Neotropics are more dependent on endomycorrhizae. Vesicular arbuscular mycorrhizae are a form of endomycorrhizae that are typified by an extensive branching network and penetration of hyphae into the roots of plants. Through the penetration of the roots, VAM distribute vital nutrients (especially phosphorus) absorbed from decomposition to the tree roots and withdraw sugars from the tree roots, providing energy for their growth. This mutualistic association is arguably the most important biological interaction in the Neotropical rainforest.

Plants: *Palms*. The vast majority of biomass in the Neotropical rainforest is plant matter, with trees comprising the bulk of this. From tiny epiphytic orchids to massive emergent trees, plants of all shapes and sizes fill the forest. It is difficult to choose one group that represents the standout among Neotropical plants, but palms (Arecaceae) are one of the most diverse groups and contribute unique ecological roles in the rainforest. Ranging from understory genera like the diminutive *Chamaedorea* to the massive *Mauritia flexuosa* (up to 35 m tall), palms are found in every type of Neotropical rainforest. *Mauritia* and *Raphia taedigera* form monodominant stands in their preferred habitats, with *Raphia*-dominated swamps in Caribbean Nicaragua and the mouth of the Amazon covering thousands of contiguous hectares. Inside the forest, small palms combine with other monocots to dominate the understory. Multiple species of birds depend on their fruits the palms depend on the birds for seed dispersal.

Insects: *Leafcutter Ants* (*Atta* spp.) (Fig. 3A). There may be as many as 10 million species of arthropods in the Neotropical rainforest, with countless species playing important roles. However, none match the magnitude and scale of impact that leafcutter

Fig. 3 Representative species of the Neotropical Rainforest. (A) Leafcutter ants (*Atta cephalotes*) are a very important insect species in the ecology of the rainforest (photo by J. P. Lawrence). (B) Three-toed sloths (*Bradypus variegatus*) represent a unique evolutionary line in the Neotropics as seen here in an important pioneer tree genus, *Cecropia* (photo by G. R. Urquhart). (C) Poison dart frogs like this *Oophaga pumilio* from Escudo de Veraguas, Panama are highly visible members of the herpetofauna in the Neotropics (photo by J. P. Lawrence). (D) The White-necked Jacobin (*Florisuga mellivora*) is a hummingbird in the family Trochilidae, a New World family of birds Photo by B. G. Urquhart.

ants have on the Neotropical rainforest. Leafcutter ants clip leaf fragments (around 1 cm round) from plants throughout the layers of the tropical forest, including the high canopy. The ants transport leaf fragments to a massive underground nest along cleared “highways” constructed by the ants. In the underground nest chambers, another caste of ants scrapes the waxy cuticle from the leaves and spreads spores on the fragment to raise a fungus that serves food for the colony. Ants harvest the fungus as food and feed it to developing larvae. The importance of leafcutter ants comes not from this unique fungus farming relationship, but from the massive relocation of nutrients that the ants perform, moving leaf material from aboveground to their belowground chambers. The leafcutters harvest a sizeable amount of the biomass production, with estimates of as high as 17% of total leaf production harvested by the ants (Cherrett, 1986).

Amphibians: Poison Dart Frogs (Fig. 3C). Amphibians play a minor role in the overall ecology of a forest, but some species stand out as unique for their remarkable survival strategies. The poison dart frogs of the family Dendrobatidae are an example of extreme aposematic coloration combined with other selective forces leading to a rainbow of colors both between and within species (e.g., *Oophaga pumilio*). The poisonous frogs of the Dendrobatidae (not all members of the family are poisonous) collect poisons from the arthropod species they consume and physiologically move the plant-derived, arthropod-vectored alkaloid toxins to the surface of their skin. Some species are highly toxic, with the Batrachotoxin found in the genus *Phyllobates* considered one of the most toxic substances known.

Reptiles: Green Iguana. Reptiles of the Neotropical rainforest are highly varied, with venomous snakes and giant anacondas receiving the most public attention and small *Norops* lizards being the most numerous. The Green Iguana (*Iguana iguana*) is a very large lizard, reaching lengths of 2 m including the tail. Remarkable about the Green Iguana is that it is completely herbivorous. It spends a great deal of time in the forest canopy, where it is one of the most important herbivores. Iguanas come to the ground to burrow a nest into riverbanks and other suitable soil. The bright green hatchlings are heavily preyed upon by many species.

Fish: The Characiphysi Fish. The Characiphysi clade of fish includes the orders Siluriformes (catfish), Characiformes (piranhas and tetras, over 1200 species in the Americas), and Gymnotiformes (knifefish). These fish possess the specialized Weberian Apparatus that connects vertebrae and auditory systems allowing for extreme sensitivity to sound, essential for living in the turbid waters found in major systems like the Amazon and Orinoco. Catfish comprise the largest percentage of fish biomass in the Amazon and range from small herbivores to the predatory Giant Amazon Catfish (up to 200 kg). Tetras include tiny “aquarium fish” as well as the large herbivore and frugivore species like the Pacu (important in flooded forest ecology described above). The knifefish not only have the Weberian Apparatus produce electrical discharges for navigating and locating prey. Together, the three orders of the Characiphysi group demonstrate the diversity and evolutionary uniqueness of Neotropical fishes.

Birds: Tanagers. The Neotropical rainforest holds both high diversity of birds (roughly 25% of all bird species) and evolutionarily unique lineages like the Oilbird (*Steatornis caripensis*) and the Hoatzin (*Opisthocomus hoatzin*). New-World-only families include the hummingbirds (Trochilidae, Fig. 3D), toucans (Ramphastidae), tyrant flycatchers (Tyrannidae), cotingas (Cotingidae), and the highly diverse tanagers (Thraupidae). The many tanager species occupy a diverse range of niches from canopy to understory, nectarivore to insectivore, with many playing important roles as seed dispersers for small-seeded plants. Often found in mixed species flocks, the tanagers are also some of the most brilliantly colored birds of the rainforest.

Mammals: Bats. Although sloths (Fig. 3B) may be the most unique mammals of the Neotropics, bats are by far the most diverse and arguably the most ecologically important group of mammals. In some countries, almost 50% of the mammal species are bats, and bats fill niches including pollinator, seed disperser, insectivore. There are even species specialized to feed on fish (bulldog fishing bat) and mammal blood (vampire bats).

Major Threats and Losses

Deforestation throughout the Neotropics has emerged as one of the greatest conservation crises of the late 20th and 21st centuries. Roughly 20% of the Amazon basin and an even higher proportion of Mesoamerican, Chocóan, and Atlantic rainforests have been deforested in the past century. Throughout the Neotropics, a variety of causes contribute but the major drivers in most regions are cattle ranching and large-scale crop production. However, the process of deforestation is often more nuanced.

Until the 1960s, large plantations and commercial logging accounted for most of the net deforestation. Small-farm agriculture in the Neotropics historically occurred on a rotational, “slash-and-burn” model, resulting in little net forest loss. After forest clearing, a small plot would be cultivated for 3–7 years until nutrient levels diminished and then left fallow to regenerate into forest. However, this changed as agricultural frontiers began to form along major access routes (rivers and highways) and were motivated by changes in the culture and politics of land ownership.

Agricultural frontiers in South and Central America are consuming tropical rainforest at an alarming rate. Different processes of frontier advancement affect the rate, but the underlying causes are often similar. Smallholder agriculture on the leading edge of the frontier is followed by larger scale replacement as the frontier advances. That is, it is often poor family farms leading the deforestation with the cleared lands eventually occupied by more permanent farms. As a result, small farms are no longer modeled on a rotational farm-fallow-forest cycle and the advancing frontier leads to great forest loss.

The Amazon basin lost 20,000 square km per year from 1980 to 2005, and has lost an estimated 20% of its total extent since 1970 (Foley et al., 2007). Cattle ranching is responsible for approximately two-thirds of the deforestation, with crop agriculture responsible for most of the rest. Logging is estimated at only 2%–3% of total forest cover loss but selective logging (which does not lead to complete deforestation) is much more extensive (Foley et al., 2007). Unlike other regions of tropical rainforest, clearcut logging is rarely practiced in the Neotropics because of a low density of high quality timber species. An alarming trend of increased forest fires in rainforests, especially in the Amazon, is likely a combined effect of logging and climate change (Nepstad et al., 1999).

Cattle ranching has long been the biggest threat to the Amazon (Fig. 4). Campaigns to address demand for rainforest beef slowed cattle-driven deforestation temporarily in the 1990s, but the increase in soy production minimized the overall improvement in deforestation rates. Soy production has emerged as a rapidly-growing threat to the Amazon rainforest. Unlike other agricultural practices that are heavily tied to labor inputs from humans, mechanized soy production can occur on a large scale with machinery doing most of the work.

Mineral mining is widespread in the Neotropical rainforest regions and contributes partially to deforestation rates. The greater risk of mineral extraction is the runoff created and the toxic chemicals used in the process. Sediment loads in rivers greatly increase as entire hillsides are blasted away with water cannons. Gold mining uses mercury to aid in the extraction process, resulting in increased mercury levels in the tributaries of the Amazon and Orinoco, where gold mining is practiced. In the Madre de Dios region in Peru, illegal mining has destroyed over 600 km² of forest (USAID, 2018). The Casseterita Mine in Rondônia (inset B in Fig. 4) covers over 9 km² and has resulted in loss of surrounding forest in ponds where mine tailings are deposited. Originally a tin mine, the discovery of gold in the mine has renewed investment.

Climate Change

Climate change impacts Neotropical rainforests in obvious and obscure ways. The most optimistic hope is that increased temperature may result in higher potential evapotranspiration if accompanied by stable or increased precipitation, allowing for greater carbon sequestration by forests. In models this holds true, but climate change’s impact on precipitation is often to reduce or change patterns of precipitation. A less obvious impact is climate change is that it has driven an upturn in the strength of hurricanes that make landfall, causing great concern for their impacts on rainforests of the Caribbean Islands and coastal Central America.

The Amazon forest is a particularly interesting case study for climate change. Because of its sheer size, the Amazon self-generates a lot of local and regional climatic conditions. Because of the prevailing easterly winds (east to west movement), evaporation in the east directly impacts precipitation in the west. When forests are cleared in the east, precipitation flows across the land surface into rivers instead of being absorbed by plants and evaporating through transpiration. Water that should enter the atmosphere and create

Fig. 4 Western Brazil and northeastern Bolivia, illustrating the pattern of deforestation that has occurred as roads and colonization policies in Brazil led to large forest clearing in the Brazilian state of Rondônia. Inset A shows a closeup of the deforestation pattern along main and side roads. Inset B is the Casseterita Gold Mine in Rondônia. Imagery sources: Google Earth. Main image and inset A are Landsat 2017 images, inset B is Digital Globe 2018.

clouds flows out to the sea, thus decreasing cloud cover and precipitation downwind from the deforested areas. The result of deforestation is thus not only loss of local forest but climate impacts to other regions of the Amazon.

Droughts are also increasing in the Amazon, from one approximately every 50 years to multiple droughts in a single decade. Major droughts in 2005 and 2010 had strong impacts on the rainfall throughout the basin and long-term impacts on the canopy of the forest. Predictions are that longer and more severe droughts are in the future for the Amazon severely threaten the forest.

Not surprisingly, forest fires are on the rise in the Amazon even though they are extremely rare in the paleoecological record for the region. Recent alarming trends of increased forest fires, and cryptic fires burning below the canopy, represent a new threat to the Amazon. Post-fire impacts have been demonstrated for canopy dieback, fruit production, large mammal distribution, understory bird abundance, and other forest health indicators.

Elsewhere in the Neotropics, climate change impacts are affecting forests in different ways. Changes in seasonality and increased severity of hurricanes are two climate change phenomena that heavily impact the Mesoamerican and Caribbean rainforests. In rainforests of Central America with a significant dry season (Belize to Costa Rica), recent years have had variation in the onset and length of the wet season. This can create an extended burning season for agricultural fires and delay the rains needed to stop these fires from spreading.

In the Caribbean and Central America, hurricane damage has increased and spread. Hurricane Otto's impact in southeastern Nicaragua and northeastern Costa Rica marks the farthest south a Caribbean hurricane has heavily impacted rainforest in recorded history. Hurricane damage is a two-pronged disaster for the forests. The minor impact is actually the wind and flood damage; the economic response to hurricane damage is often the more problematic. In Nicaragua, hurricane-damaged forests are considered degraded even though research shows they will regenerate relatively quickly and maintain their biodiversity. However, the government's response is to allow salvage logging in the damaged forests, an operation that impedes the natural regeneration and causes further physical damage to the forest. After 1988s Hurricane Joan, salvage logging operations created new roads and degraded the forest, allowing peasant farmers to enter the area and establish a new agricultural frontier that has advanced rapidly in the ensuing 30 years.

Conservation Needs

Halting deforestation is the single most important step necessary for conserving the immense biodiversity of the Neotropical rainforests. This holds true for all four major forest regions, but is especially true in the smaller Atlantic and Chocó rainforests. The Amazon has different needs as deforestation is combined with climate change impacts, damming of major tributaries, and changing economic drivers of forest loss. The Mesoamerican rainforest is primarily threatened by agricultural expansion, with highly unsustainable levels of deforestation occurring in Nicaragua and Honduras.

Of all the Neotropical rainforest regions, the Atlantic and the Chocó should be of highest urgency because of their limited extent and vulnerability to deforestation. The Atlantic forest of Brazil have already experienced significant deforestation and it continues at an unsustainable rate. Unique species like endangered Golden Lion Tamarin (*Leontopithecus rosalia*) and critically endangered Black-faced Lion Tamarin (*Leontopithecus caissara*), as well as several other endemic primates, all face the possibility of extinction if the deforestation continues in the Atlantic forest. Because a large percentage of Brazil's human population is concentrated in the regions that historically held Atlantic rainforest, the deforestation is driven by a combination of population pressures like urban expansion. The Chocóan rainforest, extending along the Pacific side of the Andes and into Panama, has experienced high levels of fragmentation, isolating its endemic species into small patches.

The overall biodiversity of the Amazon dictates that its protection should also be of high priority. Recent trends of increased crop agriculture (soy), road expansion, dam construction, and increased population need to be slowed or reversed to protect the basin's forests and species. Brazil made advances in slowing deforestation from 2005 to 2015, but the trend has reversed and the new surge of anti-environment politicians do not bode well for controlling deforestation.

The largest Central American lowland rainforests, found in Honduras and Nicaragua, are being cleared at an increasing rate as governments fail to enforce protected areas. Instead, the governments knowingly ignore the proliferation of both cattle ranches and oil palm plantations within designated nature reserves. Nicaragua's Indio-Maíz Biological Reserve and Bosawas Biosphere Reserve along with Honduras' Río Plátano Biosphere Reserve have agricultural frontiers that have penetrated far past the borders of the reserves. Active deforestation in Bosawas has reached a critical level but unwilling leaders in Nicaragua do nothing to prevent it.

Even countries like Costa Rica, with a high percentage of land in protected areas, have nonetheless experienced high levels of past deforestation outside the protected areas. Costa Rica is making advances in forest cover, but much of the "reforested" area is in the form of monocultural tree plantations with little biodiversity benefit. The future of Costa Rica's forests lies in continued protection of reserves and improved techniques for reforestation in the degraded areas between the reserves.

Examples of Positive Outcomes

Conservation initiatives in the Neotropical rainforest take on many forms, from "fortress conservation" to locally-driven participatory projects. The 1980s and 1990s saw many countries setting aside large percentages of their national territory at various levels of protected status. While some countries like Costa Rica and Belize invested in the protection of natural areas, poorer countries like Nicaragua and Honduras did not provide sufficient resources to protect their reserves.

Costa Rica. Costa Rica is often heralded as a "green paradise" where conservation has succeeded in reversing trends of forest loss. Many positive outcomes have resulted from the country's very aggressive conservation programs. The government established an extensive network of protected areas, setting aside over 27% of national territory in national parks, wildlife refuges, forest reserves, and other statuses. However, there are some shortcomings of the model adopted by Costa Rica. Although Costa Rica created an excellent network of reserves, lands in between the reserves experienced high levels of degradation as they were transformed into plantations for pineapple and bananas. In recent decades, Costa Rica has reversed this trend and experienced a net increase in forest cover, roughly 1% per year since 2005. This too is more problematic than it initially appears, because much of the forest cover increase is due to plantation forests. Overall Costa Rica serves as a positive example of Neotropical rainforest conservation, but like any solution there are also some shortcomings.

Panama. Some argue that forest conservation in Panama is a positive model for other countries (Condit, 2015). However, the historical constructs that led to the bountiful forests are unique and unlikely to be chosen by other countries. Panama's rainforests benefitted from an unusual relationship—the occupation of the central zone by the United States military from 1903 to 1999. The central area was protected to ensure the viability of the Panama Canal, with protection of the large Chagres River watershed and a buffer strip around the Canal. Reforestation occurred in treeless areas, and a healthy and diverse rainforest now occupies the buffer around the canal and the Chagres watershed (Condit, 2015).

Reducing Emissions From Deforestation and Forest Degradation (REDD+): Climate change is driven by carbon emissions, and the loss of forests globally is responsible for 11%–17% of annual global carbon emissions. Keeping the carbon stored in trees and soil represent a way to curb increasing emissions. In 2005, the United Nations Framework Convention in Climate Change developed the REDD concept as a way for wealthy, carbon-releasing countries to help protect carbon resources held in forests, particularly tropical rainforests which have high capacity for carbon storage. The REDD+ program provides incentives to developing countries to reduce emissions through protecting their forest resources. Using the general concept of payment for ecosystem services, REDD+ provides a model for results-based payments for actions that reduce forest carbon emissions. REDD+ projects are certified at three levels: Readiness, demonstration, and implementation. Projects can be developed at a national or local level. REDD+ has great potential

Fig. 5 Squirrel monkey in the Neotropical rainforest. New World monkeys have prehensile tails. Photo by Benjamin Urquhart.

to slow deforestation and provide economic value to protected forests. As with other conservation efforts, concerns do arise about who benefits from REDD+ and who controls forests in the program. It is often the desperate and poor who live in close contact with Neotropical rainforests, and REDD+ must benefit these people to be a truly sustainable mechanism for forest conservation and carbon management.

Indigenous movements: Humans and the Neotropical rainforest have not always had an adversarial relationship. For 10,000 years the Native American cultures that called Central and South America home found ways to live in the forests without large-scale environmental destruction. In the last 500 years, the indigenous peoples of the Neotropics have witnessed a blitzkrieg assault on their lands. Because imported diseases depleted their populations and they faced technological superiority of European invaders, indigenous cultures were decimated and unable to stop the destruction of both ecosystem and culture. Not until late in the 20th century did politics catch up and begin to protect indigeneity, but some countries have resisted allowing the rights that global bodies like the United Nations recognize. The result has been continued marginalization of indigenous peoples, removal from and seizure of their lands, and destruction of the territories they and their ancestors called home.

However, in some areas this trend is reversing. Indigenous groups have found a voice through international law and a willingness of philanthropic foundations to help support their efforts to reclaim their lands. In southeastern Nicaragua, the Rama people have taken protecting the Indio-Maíz Biological Reserve into their own hands after watching the national and regional governments do little to protect it. They have established forest patrols to monitor illegal colonization and are appealing to the government for help removing illegal settlers. In northern Nicaragua and Honduras, the Miskito are trying similar tactics. In Ecuador, it is the Huaroaní trying to balance oil extraction with protecting their native lands. In Brazil, several indigenous groups are fighting back against plans to dam the major tributaries of the Amazon. Throughout the Neotropics, indigenous led conservation efforts represent the uprising against unsustainable agricultural frontiers, gold mines, dams, and logging. With great hope, the indigenous people and conservationists hope that the 21st century can be a change from the way cultures originated in Europe have treated our most precious biome, the Neotropical rainforest.

Conclusion

The Neotropical Rainforest is the most biodiverse—and arguably most important—biome on the planet. High levels of both plant and animal biodiversity occur on a local and regional scale, creating areas where in a single 100×100 km cell, more plant and animal species are found than in the entire temperate portion of North America. Each of the four major regions (Fig. 1) of Neotropical Rainforest has unique species and conservation priorities (Fig. 5). The greatest threat to all regions remains deforestation, but in each region different drivers of deforestation come into play. Climate change increases the likelihood of fire and the severity of hurricanes, exacerbating the losses due to deforestation. Conservation efforts must recognize the nuances of biodiversity and the coupling of human activity with the natural systems to generate long-term solutions to one of the greatest crises facing humankind—the loss of the Neotropical rainforest.

Abstract

The challenges of conserving Old World Tropical Rain Forests range from direct human impacts to the unanticipated consequences of conservation policies, not to mention that the rate of global warming is outpacing the capacity for the region's plants and animals to adapt in a balanced manner. The biodiversity is irreplaceable of the rain forests found across the African and Asian basins. Even if we completely preserved the rest of the planet's tropical ecology, the Old World spreads over so many physiographic domains that it is unmatched in its endemic species throughout the Earth's biomes. The brief description herein of the Old World tropical rainforests is only a glimpse of those values, but the threats to them are readily detailed. What is happening, where it is occurring, why forest impacts exist and spread, and when did it start all inform attitudes of how we should react. Clearly, humanity needs to stop the loss of forest habitat, but we must also take action to restore forests in a technically sound fashion. Who should do this work? Everybody has a stake: the adverse impacts to our atmosphere mean that no nation or people can escape these losses, and each decade sees us closer to the time when we would be forced to live without these resources. Due to the broad physical range and biological network of the forests of tropical Africa and Asia, their preservation could offer refuge to survivors of the future, including plants and research opportunities that give us life-saving medicines. Oh, and our most precious animals live in these regions: Elephant, Rhino, Orangutans, Lions, Snow Leopards, and more birds than we can count!

It is not coincidence that the richest forest ecosystems are in the tropics, where so much legend arose during the 1700–1800s. Tropical forests are a global resource where the sun and water combine to drive much of the globe's hydrology. These irreplaceable habitats are threatened by climate change, human population growth and resource extraction. Here we discuss the richness of Old World Tropical Rainforests (Fig. 1), but unfortunately, must spend too much effort discussing the threat of forest loss. The silver lining is that by addressing the facts of, and possible actions against, forest loss, we educate and motivate society to prevent the losses by properly protecting and managing the forests we have.

The questions surrounding forest cover change are not simple, especially in rainforests where even the smallest break in canopy is met with a rush of volunteers to take it back over. When there is regrowth of forest, is it likely to return an area to its original ecology? Should we resist such changes, even though they may result in more forest cover? Must conservation policy accept only preservation of existing forest, or do we attempt restoration in answer to inevitable anthropogenic losses? AND, what must we know to determine how to direct the preservation or recovery?

Ecological theory guides conservationists as they prioritize investment in habitat protection and restoration because funding for the environment is limited. Theorists create tools to decide how to select locations, areas and species that are to be restored or preserved. While a review of the many efforts to create such guidelines is beyond the scope of this article, the questions addressed herein underpin forest conservation. Clear examples of how such protection efforts succeed include regulation of wetlands in the United States, global programs of Marine Protected Areas, various national parks programs, and of course, the many laws concerning endangered species, both national and international. In a review of global biomes, Watson et al. (2016) show that tropical and subtropical moist forests comprise 15% of the world's biomes, and of that only 12% is still considered wilderness, but there are a remarkable 11 World Heritage Sites within this biome.

Fig. 1 Global view of tropical forest regions.

Scientific Significance of Old World Tropics

Legends reflect the historic fascination of Europe with the African and Asian ocean basins, opening those regions to commerce and eventually challenging humanity to understand how to manage their natural wealth. A child's imagination about "far-away" places often reaches to the savannah of Serengeti, where lions roam, or the jungles of the Congo where Stanley tried to meet Livingstone the historic missionary, or the jungles of India where Rudyard Kipling teased our minds about colonial escapades of tigers and panthers. Now, our experts must teach us how to conserve those resources.

Roughly half of the global forest loss is in the Old World areas (Curtis et al., 2018), much of it tropical (Fig. 2) (Hansen et al., 2013). It is ironic that at the outset of creating this article, a major study was published that challenges the biogeographical basis for labeling the Old World versus the New World regions (Slik et al., 2018). So, aside from the sheer bulk of habitat, ecosystems and wildlife housed and threatened within Old World Tropics, these regions continue to be at the heart of the theoretical basis of ecology. This "taxonomic/biogeographic challenge" is so new that we have decided to use the existing definition of these regions in this article. Suffice it to say, this debate will be critical to future literature, so the reader is warned to pay attention to that debate. For now, however, we consider Africa to southeast Asia as "Old World," and the American continents as "New World," since the literature to date takes that perspective.

The high species richness and diversity of tropical forests, especially rain forests, provides ecological theorists challenges in explaining global patterns of nature. Through these studies, we are actually learning how life developed and protects itself, lessons from which humans can learn about protecting the resources we depend on. Are life patterns predictable? Or are the patterns we observe in life all random (as posited by the “Neural theory” of evolution). Tropical forests are fertile ground for testing theories of biodiversity and ecological resilience: [Molino and Sabatier \(2001\)](#) showed us that tropical forests adhere to the “intermediate disturbance hypothesis,” which states that the highest numbers and diversity of species occurs at stages of intermediate recovery from disturbance. Such studies in tropical rainforests produce results faster than elsewhere because life cycles turn over so quickly in wet and warm habitats. Accordingly, [Ricklefs and Renner \(2012\)](#) were able to address neutral theory and showed that communities are formed in response to such dynamic factors as animal behavior and habitat structure using comparisons of similar tropical forests in South America, Africa, and Asia.

In addition to the academic value of tropical forest studies, the reason we care about Old World Forests is that the ground they sit on provides irreplaceable ecosystem services, functions that are maintained by the mosaic of original forest types. The soils, water and air that support Earth’s life are present in a special mixture, and as with any recipe, if the proportions of ingredients are changed, the product is changed. [Kooyman et al. \(2013\)](#) showed us that forest loss and recovery does not follow an intuitive pathway, and that the more opportunistic species (vines and other pioneers) do not need intervention to protect them, while the mature canopy trees are easily threatened. Failure to understand such dynamics in conservation planning can translate to losing some species forever. This process is already documented because the pace of climate change is outstripping the original natives by advancing competitors not originally dominant in a given area ([Curtis et al., 2018](#); [Pradhan et al., 2018](#)). The shifting of wildlife geography is a threat to natural migration, because migration evolved in concert with the rain cycles, for example, on grasslands. Climate change is occurring so fast that it forces changes in plant and animal assemblages that are no longer in concert with the behavior patterns that took eons to evolve at a much slower pace.

Tropical Forest Types and Locations

There is no one “tropical forest,” or a single type of “rainforest,” so we begin here by reviewing the wide range of forest types within the biogeographic region termed “tropical.” When most people think of “tropical forests” the stereotypical overgrown tropical rainforest from tales such as “The Jungle Book” most likely comes to mind ([Photo 1](#)). However, even within the tropics, ecosystem subdivisions can be made mainly based on the length of the rainy and dry seasons, but are not so clear cut because these habitats change so quickly when disturbed. Across the tropics there is a gradual transition from wet (rainforest) to dry (savanna) as one moves away from the equator, or into areas that lack the rain to sustain rainforests. Within each tropical ecosystem there is a great deal of diversity, and it is impossible to describe their intricacies in one short article. However, what we provide here serves as an introduction to the three main tropical biomes ([Table 1](#)) ([Brown and Lugo, 1984](#)) and the diversity of tropical, woody ecosystems, showing the context for rainforests themselves.

Tropical rainforests are the most biologically diverse and complex forests on earth. They grow around the equator in South America, Africa, and Southeast Asia, within the area bounded by latitudes 23.5°N and 23.5°S. Tropical forests are characterized by their stable, warm temperatures, high rainfall, and distinct seasonality. There are only two seasons, rainy and dry, and the length of daylight is around 12 h with little variation. Tropical forests are known for their wide range of flora and fauna, including many endemic species, having the highest species diversity per area in the world. Furthermore, tropical forests also play a critical role in mitigating climate change because they act as a carbon sink. Despite the beauty and importance of tropical forests, they are rapidly disappearing around the globe, mostly due to anthropogenic pressures. More than half of tropical forests have already been

destroyed. For example, approximately 48 million hectares (ha) of these varied tropical forests, an area larger than the state of California, were cut down between 2000 and 2005 (Hansen et al., 2010). The drivers of deforestation differs amongst forest types as well as amongst geographical regions. Here we will discuss the types of tropical forests and where they are found, and the threats to these unique and important habitats.

The complexity of ecological responses to different rain and temperature regimes (along with variations in elevation and soil conditions) is nearly infinite. This extreme capacity for variations is precisely the reason that rainforests are so threatened: the plants available to “invade” or take over from the original species in a given patch of forest make it very difficult for the original assemblages to persist once disturbed (Kueffer, 2017). Unfortunately, when changes occur to the plant assemblages, the wildlife are not generally as adaptable, so disturbance favors opportunists, and disfavors endemic species which are adapted to an original and narrow range of physiographic conditions.

Tropical Rainforest

Tropical rainforests grow close to the equator, between 10° north and south. Tropical Moist Forests are characterized by low variability in annual temperature and high levels of rainfall (>200 cm annually), with either no or a short dry season. The temperature is stable year-round, around 27 °C. The high temperatures, abundant rainfall, together with 12 h of light a day promotes the growth of many different plants and results in large trees that are green year-round. The trees grow very densely together and the branches and leaves block most of the light from penetrating to the understory (Photo 2). The soil can be several

**Photo 2** Typical view of rainforest understory.

meters deep, but due to nutrient leaching, it lacks most of the essential nutrients for plant growth. The thin topsoil layer contains all the nutrients from decaying plants and animals, and this thin layer sustains the many plant species in the forest. Forest composition is dominated by semi-evergreen and evergreen deciduous tree species. The tropical rainforest biome covers about 17 million km² in three regions: Southeast Asia, Central Africa, and Amazonia. Human use has affected >20% of this area, with approximately 20% used as pasture or cropland in 2000 (Ramankutty et al., 2008). Tropical rainforests have the highest species diversity per area in the world, containing millions of different species. Even though they cover only a small part of the earth, they house at least one half of all species. As you can tell from the name, it rains a lot in these forests.

Tropical rainforests are fragile habitats that are sensitive to plowing, overgrazing, and excessive burning due to their high moisture and thin nutrient-poor soils (Mann, 2002). The plant species inhabiting tropical rainforests have a somewhat unique ability to take advantage of nutrient poor soils with characteristics that somewhat echo the traits of invasive species, and result in their high biodiversity. However, due to the rapidity with which changes can occur in the rainforest species assemblages, these habitats are also in delicate balance, and it is too easy for them to lose their natural species combinations when the soil, water or canopy are disturbed.

The transition zones from wet to dry habitats are crucial regions across the globe, partly because climate change is shifting these lines (Pech et al., 2017), but also because there are significant “edge-effects” between biomes (Pfeifer et al., 2017). Habitat edges provide unique habitat and refugia that allow species to transition between habitat types. Habitat changes are occurring at rates that exceed the capacity of ecosystems to “evolve” naturally (Siepielski et al., 2017), thereby elevating the threat to their survival. Hence we cannot predict the results of climate-driven adaptation in such dynamics systems, so we are limited in our ability to aid plants and animals by proactive management.

Tropical Savanna

As one moves further from the equator the forests gradually transition to savannas, which have a few trees but are mostly vast landscapes of grasses and shrubs. Large expanses of land in the tropics do not receive enough rainfall to support extensive tree cover. Here, the wet season is short and the longer dry season leads to more frequent fires. These factors combine to suppress the growth of trees and allow grasses to dominate, although scattered trees may be common. Savannas are prevalent just south of the dry forest in northern Australia, and in parts of Southeast Asia. However, African savannas are the most well known and are famous for their diverse and abundant wildlife. In Africa there are large areas of savanna that cover the landscape south of the Sahara Desert. The savanna biome covers 20 million km², or about 15% of Earth’s ice-free surface. Of this area approximately 50% was used as pasture or cropland in 2000 (Ramankutty et al., 2008). There is a diverse assemblage of large mammals that have evolved to take advantage of these habitats. These ecosystems are mainly threatened by climate change, which is causing the spread of wet areas, resulting in more tree growth as moist forests expand.

Tropical Dry Forest

Discussions on vegetation in the tropics often focus on shifts between forests and savannas, but ignore dry forests. However, tropical dry forests are distinct from moist forests in their seasonal drought and consequent deciduousness and differ from savannas in that they rarely experience fire. Although the tropical dry forest biome may be less well known than tropical rainforest or savanna, it is the most threatened of the major tropical forest types (Jansen, 1988). Identifying dry forests is a complex issue, as dry forests grade into other vegetation types such as wet forests, savannas and woodlands. However, in simplest terms dry forests may be defined as forests occurring in tropical regions characterized by pronounced seasonality in rainfall distribution, resulting in a dry season that spans several months. Most tropical dry forests are between 10 and 25° north and south of the equator. Dry tropical forests, with their longer dry seasons, are dominated by deciduous trees which have a leafless period during the dry season. This loss of leaves opens the canopy layer, enabling sunlight to reach ground level and facilitate the growth of thick underbrush. It is estimated that only 1,048,700 km² of tropical dry forest remains, distributed throughout the three tropical regions, with over 50% found in South America, and the remaining half in Africa and Asia (Miles et al., 2006). In Africa, tropical dry forests are extensive across many parts of the continent, extending to the north, east, and south of the Congo Basin rainforest. Tropical dry forests also cover much of India, extend into parts of China, and are a major type of land cover in Australia. Though less biologically diverse than rainforests, tropical dry forests are still home to a wide variety of species, many of which display extraordinary adaptations to the difficult climate. Virtually all of the tropical dry forests (about 97%) that remain are currently exposed to a variety of different threats, largely resulting from human activity.

Unique Ecological Characteristics = Endemism

If we accept the definition of Old World as being the Africa-Asia basins, it is a region with a large proportion of the planet’s endemic biodiversity, some of it still very remote. The preservation of endemic species (i.e., those found only in a given region or site) is perhaps the most critical of conservation objectives because many of these species cannot find new homes as the planet changes, so they would be lost forever. Why is that important? The particular characteristics that contribute to isolating species from other regions allows them to evolve unique, endemic genetic profiles, but these same traits “trap” them in their home region, confirming

Fig. 3 Estimates of the number of species impacted by human activity. Reproduced with permission from Allan, J.R., Watson, J.E.M., DiMarco, M., O'Bryan C.J., Possingham, H.P., Atkinson, S. C., & Venter, O. (2019). Hotspots of human impact on terrestrial vertebrates. *PLoS Biology*. <https://doi.org/10.1371/journal.pbio.3000158>.

theories of natural selection. The extent of the threat to wildlife in the rainforests of Indonesia and Malaysia are more severe than elsewhere (Fig. 3), and the level of endemism is so high that these are potentially catastrophic.

The habitat which comprises rainforests is multi-dimensional and dense, which is often difficult for a casual observer to see (Photo 3). Can you see the “trail” that our leader followed? But the wildlife using such habitat is adapted to patterns and “layers.” The layers can be characterized by physical parameters: the understory (ground level) is hot and wet, with no wind, and only minimal, reflected sunlight under a closed canopy. At the top of the forest, within the canopy, sunlight is absorbed, and rain and wind have distinct effects. The mid-layer is inhabited by epiphytes. Often found in pockets created between tree limbs, these plants are not rooted in the ground, because they thrive using moisture, carbon dioxide, etc. from the atmosphere. Within and just below canopy are an array of micro-habitats that are important for food production. Nutrient recycling beneath the canopy occurs amongst the mosses and lichens, creating organic habitat for exotic plants (e.g., orchids and bromeliads).

Photo 3 People walking along a rainforest trail.

The widely varying micro-habitats created by the mosaic of plant and animal species in rainforests result in too many assemblages to review in this article, but some examples of remarkable species are briefly described.

Kapoc (*Ceiba pentandra*) is one of the largest tree species in the world, reaching two hundred feet tall with a trunk diameter of nine feet; these trees came from the New World in their global spread. Shorea trees (*Shorea gratissima*), members of the dipterocarp family, are the most common tree in the rainforests of Southeast Asia (the species is often >10% of the trees in a typical canopy layer). Custard Apple Trees (*Annonaceae*) are common in the Philippines and Africa. Other common tree families are Rubiaceae, Lauraceae, Leguminosae, Rutaceae, Apocynaceae, and Solanaceae. "Strangler fig" (*Ficus* spp.) represents several species of fig tree, a plant that winds its way up any vertical object, such as rocks, other trees and even buildings. The vine is actually strong enough to strangle its host. Figs are important food for bats and its various forms ensures some fruit being in season all year. People eat figs and use the plant material in varied ways. There are a variety of plants in the tropics that have symbiotic relationships, such as Cecropia trees who rely on fierce ants to defend them against depredation by wildlife and insects. These ants can even attack other plants when they overgrow their host (Fig. 4) (Lawton, 2018).

As a popular illustration of the unique character of rainforests, conservationists point to the many wildlife species that are indigenous to specific geographic areas. On Mount Kenya is a stand of Bamboo (*Yushania alpina*) in the rainforest belt where Elephants roam with Leopard. In Uganda live Mountain Gorillas amongst the Ruwenzori Mountains, and an endless array of primates living in the Congo's rainforest. In Borneo there are Clouded Leopards and Orangutans dependent on rainforest habitat which is fast being fragmented (Laurance and Watson, 2016). And in India, the Bengal Tiger is running out of habitats in which to seek refuge (Ranganathan et al., 2008).

It is important to note that the global problem of "invasive species" has long been the bane of rainforests. These "pioneer species" grow in the rainforest understory as soon as the canopy is broken by fire or other causes of clearing (natural and anthropogenic). Pioneers are the fastest growing species in any habitat because they are adapted only to rapid growth, and do not have the long term biological defenses against molds, bacteria and viruses, or retardants to wildlife depredation. But they quickly cover the ground needed by slow growing Kapoc and the *Dipterocarpaceae*, species which can dominate given time and suitable hydrological conditions. Once established, the larger species gain the advantage of blocking light to the pioneers. A natural

Fig. 4 Map of impacts of road development. Modified from Lawton G. (2018). Road kill. *New Scientist* 36–41.

understory provides food for wildlife and people: bananas, mango, papaya and oil palm. Spices and medicines are abundant in rainforests.

Here is where the story of rainforests becomes troublesome: palm trees grow so well and provide palm oil. Palm oil trees are native to West Africa, favoring riverine and wetland habitats. The disbursement of this plant across the globe is associated with a rush to generate income from the oil as a substitute for many uses, including cooking and cosmetics. Although palm oil represents substantial wealth for farmers in the tropics, the clearing of native woodlands for its production has created a crisis in all tropical habitats, especially rainforests. In Malaysia and Indonesia the loss of such habitat has impacted many animals, like orangutans, with extinction as a direct threat from palm oil plantations. The conservation threats to tropical forests are discussed below at length.

What is Happening to Old World Tropical Forests?

The impacts to forest cover across our planet are as diverse as the many cultures living amongst these habitats. These impacts include clearing of forests, sale of wood and wood products and ancillary impacts such as global warming that threatens entire ecosystems, changing rainfall patterns, wildlife migration and even soil microbiology (Abrams et al., 2017; Morris et al., 2016). The growth of the human population on Earth has caused the loss of all habitats, and this is especially true in Africa and Asia as such forests have long been harvested for their natural resources, such as unique hardwoods. The abundant sun and water in the tropics encourage local populations to grow crops wherever open ground can be found or created by woodland clearing, to support local, developing economies. The loss of forest cover since humans advanced agriculture is estimated at 35%, and people have impacted >80% of the remaining 40 million km² (Watson et al., 2018). Logging and clearing have had ecosystem level consequences throughout the tropics, such as the cascade of impacts to wildlife from the loss of habitat (Bello et al., 2015; Erb et al., 2018).

The cascade of wildlife impacts has already begun, for example in the southeast Asian rainforests, where an obscure species, the moonrat (*Echinosorex gymmura*), is clearly losing its population continuity in the pathway of oil palm plantation development (Brozovic et al., 2018). In general, such small mammals attract little attention, but they are usually survivors, so their fate is a strong signal of trouble for the region's rain forests. In the Gorongosa National Park of Mozambique, the loss to human pressure of leopard and African wild dog has led to a cascade affecting first vegetation, and eventually the whole park. Atkins et al. (2019) explain how the loss of these top predators spurred the spread of bushbuck (*Tragelaphus sylvaticus*), which expanded their foraging into floodplains, and consumed a novel diet including waterwort (*Bergia mossambicensis*). This change in foraging behavior and diet creates multiple impacts: the bushbuck is exposed to new dangers in open range, and the other species that forage on the waterwort (including humans who use it also for medicinal purposes) have new competition.

There are two major ways in which habitat is destroyed, some by people knowing they are cutting forest, and some as indirect consequences of other practices, such as road and infrastructure development. In a historic sense, it took many centuries before humans recognized they were harming their world, and still certain harmful practices are not fully recognized and regulated.

The incursion into forests in Africa, for example, when it was done simply by manual labor or unsophisticated machinery (e.g., 19th or early 20th century rudimentary agricultural equipment) was a starting point for habitat loss, albeit a modest impact. Accordingly, these traditional and historic practices were slow, and the forest was able to recover to a certain extent because of the immense effort required to clear truly large tracts. But with "modernization" of land development since World War II, and in the current age of globalization, the pace and scope of the threat is far more severe.

The road and corridor development process in emerging nations has reached epidemic proportions, and in 33 planned or developing transportation corridors across sub-Saharan Africa, there are direct impacts to 69 key Protected Areas (PAs) (Sloan et al., 2016). Amongst these PAs are sites designated as RAMSAR, World Heritage, National Parks, UNESCO Reserves, all deemed significant on a global scale and to which substantial social, economic and political commitments have been made. The challenge now is to understand the importance to local communities of the commercial value of the transportation and who actually benefits from the initiative to "modernize" remote regions, and is amongst the most important policy issues of this age.

It is not always simply forest loss by logging or burning that is a concern, but rather management (or lack thereof) can also be a problem. In southeast India, in the Odisha region, the Andhari Sacred Forest is a dry forest which offers a window into understanding the ecological history of such woodlands because it, and a number of other forest patches in the region, have benefited from cultural protection (Pradhan et al., 2018). The species richness and composition of these protected areas are higher than control sites, but they also demand special management since natural turnover is suppressed, so species that regenerate more robustly are taking over.

The similarity in biological traits between native and invasive species results in tropical rainforests being susceptible to take-over by foreign species. While invasive species have the potential to permanently eliminate a natural species assemblage, some of them are desired by local people. In Madagascar, the Guava tree (*Psidium cattleianum*) can provide food and even income if grown in abundance for export. In Asia, Wild Ginger (*A. angustifolia*) is both a medicine and food resource. The bead tree (*Adenanthera pavonina*) and Bamboo (*Bambusa vulgaris*) are widely introduced as landscape species, but once in the vicinity of natural habitats, these spread and take over with their aggressive style of forming thickets with deeply rooted systems so hard to exterminate. Some species, like the shrub Siam weed (*Chromolaena odorata*) observed in Tanzania possess powers of allelopathy, whereby their biochemistry produces compounds that retard competitors. Some species, such as a Mahogany (*Swietenia macrophylla*) in Asia, offer a potential for forestry production with high monetary values.

The relationship between biodiversity and endemic species is complex: when endemic species disappear from a habitat, invasive species take over. Invasive species have the advantage in general of being able to live in conditions that are marginal to them, that is how they invade, and after establishing in a new area, they begin to convert it to conditions that prevent the original species from living there. There are limited programs to control invasive species, which are mostly aimed at isolated patches along roadways, adjacent to or on farms, in suburban areas, etc. However, the control of invasive species in rainforests, where clearings occur due to people's activities, is a pursuit not widely addressed.

In a case study of the Bamburi Cement plant in Mombasa Kenya, a regrown forest was justified because it replaced ancient coastal reef structures, where no other forest would ever exist anyway. The selection of suitable tree species was aimed merely at rapidly covering a mining operation, and the ecosystem services were simple: erosion control, soils recovery, water quality protection and wildlife habitat. If there had been an objective for a specific type of wildlife assemblage (e.g., game farming), more attention would have been paid to the species of trees and resultant forest type.

For example, one strain of the common reed (*Phragmites australis*) spread around the world during the 16th to 19th century as ships went between the south Pacific and the Atlantic, and now the species is excluding the endemic strain in North America. *P. australis* converts a coastal wetland from a tidal cycle marsh to a marginal, raised substrate, which eliminates the habitat that served as a nursery to so many finfish. And of course, there is a cascade of adverse effects: the high level of filtering provided by the marshlands is lost and the birds that relied on these finfish nurseries for food are reduced as their habitat degrades. This process occurs in the tropics and temperate zones, and rainforests as oil palm, for example, replaces native species assemblages. While oil palm 'invades' by intentional planting, species of the families *Myrica* and *Mimosa* are spread to forest openings by wind and wildlife, and lead to long-lasting changes in habitat quality.

When is Old World Forest Loss happening?

Common sense tells us that forest loss is a continuing process related to a variety of factors. The history of forest loss is glimpsed in two recent studies: [Curtis et al. \(2018\)](#) report forest loss in Africa and Asia (not necessarily all tropical, but mostly) of 150 million hectares between 2001 and 2015, or a rate of 1 million hectares per year! The study by [Aleman et al. \(2018\)](#), looking at data from 1900 to 2000, reports forest loss for all tropical African areas studied as 21.7%, or 754,000 ha year⁻¹. The recent advances in satellite telemetry allow the resolution of forest loss at finer spatial and temporal scales than ever before (e.g., 3m², daily images, [Finer et al., 2018](#)), and it is critical that globally coordinated monitoring be maintained. By 2007, desperation calls from Borneo warned that this ecological refuge may be the last hold-out for Asian tropical rainforest ([Stone, 2007](#)).

"This is the only place [in Southeast Asia] where tropical rainforest can still be conserved on a large-enough scale to remain permanently viable," says Rahimatsah Amat, chief technical officer for Borneo with the World Wide Fund for Nature (WWF) in Malaysia.

An understanding of the problem of "When" is highlighted by [Alamgir et al. \(2019\)](#) from their analysis that shows how road and rail planning underway now threatens contiguous forest in Indonesian Borneo (Kalamantin) as soon as the funding can be put in place. The historic condition of Borneo's forests will be divided by transit corridors to a greater or lesser extent as the roads and rails develop. Central Africa, Indonesia, Malaysia, Borneo, Solomon Island region all provide some refuge to rainforest habitat and wildlife, and face the growing threat of sea and land links to meet the economic demands of these nations ([Fig. 5](#)). And the creation of transportation corridors is breaking up habitat for seriously endangered animals, such as the Tapanuli orangutan (inset, [Fig. 5](#)).

Where is Old World Forest Loss Happening: Regional Considerations?

Forest loss or disturbance is global, and accelerating as emerging nations seek the wealth and "modern" advances they observe in Europe, China and North America. Over the years 1982 to 2016, the planet experienced a net gain in forest, but the tropics actually lost about 4% of its cover. In a comparison of tropical forest loss, the Old World tropical forests in the Congo and Miombo woodlands of central and west Africa, as well as Asian areas in Vietnam, Myanmar, Cambodia and Indonesia, along with parts of Queensland, Australia, were all impacted by smallholding agriculture and more recently, crop-based commercial farming ([Song et al., 2018](#)). Following the classic definition of "Old World," a comparison by [Saatchi et al. \(2011\)](#) shows us that half of the carbon stocks of tropical forests are in South America (49%) and half in the forests of sub-Saharan Africa (25%) and Southeast Asia (26%). Hence the "Old World" holds half the bio-carbon of the forests, and also much of the untapped mineral and fossil fuel resources. These resources, combined with a desire by local people to achieve "modern wealth," means there is no sector of the planet that is not under threat from forest loss. The summary of threatened species hotspots across the globe makes this abundantly clear ([Fig. 3](#)).

Why is Old World Forest Loss happening?

There are two broad answers: economics and climate change. A simple answer is that local economies want to garner the wealth promised by the resources at hand, cutting trees for firewood, clearing land for smallholding agriculture and more recently, a move to create incomes from global demand for such crops as palm oil. The "why" of forest loss also has some arcane elements which are

Dammed to extinction

The entire population of Tapanuli orangutans lives in three patches of forest in northern Sumatra. A planned hydroelectric dam will cut off connections between them and probably doom the species

Fig. 5 Road density in the Old World and its consequences. Modified from Lawton G. (2018). Road kill. *New Scientist* 36–41.

just now becoming clear: global warming changes terrestrial ecosystems, and no part of the world is left out of this pattern (Nolan et al., 2018). This warming causes crop loss to insects which benefit from higher temperatures, quite notable for wheat, rice and maize crops in central Africa and throughout India and Southeast Asia (Deutsch et al., 2018). Loss of crop productivity encourages people to clear more woodlands to expand their income. And it is a short step from clearing for local agriculture to clearing for industrial scale resource extraction (e.g., oil, gold, uranium, rare earths, etc., Abrams et al., 2009).

What Do We Do About Forest Loss: Conservation Considerations?

The human response to any environmental disaster is generally twofold: prevent it and/or replace the lost resource. While many lessons have been learned about habitat restoration and replacement, a first question is: Are we too late? Then we need to prioritize our actions as we consider the alternatives. If we choose to restore habitats, how do we know what should be the model forest in a given location, which habitats are most valuable?

Ironically, one of the signs of degradation is the spread of woodlands where grasslands once dominated. Philosophically, the reaction of conservationists and policy-makers alike is to wonder if we should just live with and justify the changes. Will conservation policy resist forest losses, or adapt to life without the remarkable tropical forests? Simply put, will humanity make the necessary effort to preserve our atmosphere and hence our terrestrial habitats. It is imperative that the losses of woodlands be defined and their ecological processes understood. A comprehensive look at forest changes between 1900 and 2000 shows that global forest losses have been poorly studied, and that in fact, in certain areas there are actually numerical gains in tropical forest as savannah grows into woodlands (Aleman et al., 2018). Yet, we do not know if such 'gains' should be conserved or resisted.

The changes in global forest cover have many causes and consequences, ranging from shifts in wildlife populations (Allan et al., 2019; Woolley et al., 2008; Fullman et al., 2017) to suppression of fire (Abrams, 2015). The most disastrous cause-affect cycles are global warming and changes in rainfall which change habitat so fast that neither plants nor animals can adapt (Watson et al., 2018; Lézine et al., 2019).

Forest Protection/Preservation

The global effort to preserve open spaces, whether these be forests, grasslands, wetlands or marine protected area, began a mini-boom at the dawn of the 21st century. The IPCC had reached global acceptance with the Paris Agreement, within which was the proof that tropical forests provide not only enormous biodiversity benefits, but also sequestered the carbon dioxide that was shading Earth, making it warmer and warmer. The United Nations promoted the Interfaith Rainforest Initiative with their expressed mission: *The Interfaith Rainforest Initiative is an international, multi-faith alliance that works to bring moral urgency and faith-based leadership to global efforts to end tropical deforestation* (www.interfaithrainforest.org). The IRI works in Congo and Indonesia in the Old World region.

Rainforest preservation involves the complex issues of land ownership, local economic dependence on wood and demand for agricultural production. During the 1990s, as an awakening began about forest loss, a hope was expressed by Bawa and Seidler (1998) that parkland management might be an answer, but they acknowledged a lack of data to study the effectiveness of parks and preserves. Now, 20 years later, Bowker et al. (2017) have assembled data showing how parks in sub-Saharan Africa have reduced forest loss especially where human access is controlled. Burivalova et al. (2017) have shown this effect in Papua New Guinea using innovative technology that reads “soundscapes” to assess human presence. Clearly, the conservation of tropical forest is enhanced when land-use activity is controlled, be it through remoteness or local commitment (Fig. 6).

Replacement (Natural Recovery, Restoration)

For decades there have been examples of forward-thinking corporations, academics or individuals who have recognized and taken action against forest loss by planting trees or preventing mowing/burning. However, these disparate forces were only unified on a global scale for the sake of forest conservation during the late 20th century when the specter of climate change was called out at the 1992 Rio Conference. In the rush to respond to the early REDD initiatives which arose in the 1990s, particularly in southeast Asia, good concepts fell victim to abuse. Eventually the practice of cutting a woodland and then asking to replace it with REDD funding was halted in REDD+ as rules for the program were tightened.

So, how does one rebuild or restore forest habitat, and where and why is it happening? Early efforts began long ago, tied to commercial wood production, and focused on native or introduced species that grew quickly and produced large quantities of saleable wood. On a parallel track, conservationists began asking... How do we know what to plant? Can we combine commercial wood production with conservation of natural ecological communities? These remain the leading questions in the 21st century, and Cernansky (2018) reminds us at the ecosystem level to ask ourselves “...about matching trees to their locations, about the effects on nearby insects and other animals and about relationships with soil and the changing climate.”

Some progress on forest recovery has been reported, for example, in East Africa, but the challenges in just ecology alone are substantial. Chapman and Chapman (1995) and Cordeiro and Howe (2001) found particularly slow tree recruitment, and also slow growth in trees that were planted from cuttings, because savanna grasses and shrubs are so much more effective in capturing nutrients and moisture. In Kenya, a unique project used the Asian tree, *Casuarina* to restore lands scarred by mining (Abrams, 2018).

Fig. 6 Empirical comparison of types of preserve areas that conserve high carbon (i.e., biomass) under different ownerships (Abrams, 2011 from concept in Chhatre and Agrawal, 2009).

Conclusions

It is particularly difficult to measure climate induced changes in a place so diverse and ever changing as a rainforest, making this irreplaceable habitat an easy target for our abuse of the environment. There is ample proof, though, that if we manage native habitat by blending ecological theory with local knowledge, we can generate substantial gains in saving habitats that will sustain themselves to a greater or lesser extent. If intervention is necessary, it must be entirely for the benefit of the habitat, not simply for economic profit. Conservationists are accustomed to limitations, and are fully aware of economic pressures on land owners and government. But if scientific planning is given the license to direct land use and it is focused on resource protection by local jurisdictions, both people and nature can persist. The prevailing fear amongst conservationists now for the regions holding tropical rainforests is that the global push to spread “modernity” will not honor the ecological resources in those areas. There is a bona fide threat here because so many of the people of emerging nations seek the advantages garnered by the developed nations, and we can only hope to help them recognize the values they already have in their forests as conserved habitats.

Abstract

The elevational gradient at the Cofre de Perote in the central region of Veracruz State (eastern Mexico) is considered as one hotspot of plant diversity in the Neotropics. This is mainly due to the landscape heterogeneity and transition between biogeographical areas. In this study, we assessed the distribution patterns of vascular plant diversity, the underlying abiotic factors, and the impact of anthropogenic disturbance on floristic diversity. We treated the most relevant aspects of the composition and diversity of the vascular flora present within the different forest biomes along the elevational gradient, as well as the environmental problems of the region in which it is immersed. For this, we took ferns (terrestrial and epiphytic), terrestrial herbaceous angiosperms and shrubs as representative examples. We established a method of studying local plant diversity through sampling plots of 400 m². These plots were distributed in eight different elevational belts (six vegetation types) from the sea level to 3500 m, approximately every 500 m in elevation. Furthermore, we sampled in plots at different habitats (i.e., old-growth forest, degraded forest and secondary forest) in order to study the impact of the anthropogenic disturbance on plant diversity within each elevational belt. Our results showed a total of 551 vascular plant species (6.4% of the State's and 2.3% of the country's flora). The highest diversity of each study group was found at different elevations, mainly in areas with presence of humid montane forest. The highest diversity of terrestrial and epiphytic ferns, as well as terrestrial herbs, was found in mid-elevations between 2000 and 2500 m. The richness peak of shrubs was found generally in areas below 1000 m. Both extremes of the elevational gradient present contrasting climatic conditions in different periods of the year which limit the presence of a high diversity of the studied plant groups. A large portion of the flora is affected by anthropogenic disturbance. Thus, it is necessary to establish conservation plans for the area that include interconnected fragments to allow the dispersal of species.

Introduction

"Nowhere else it is possible to see better the admirable order of the different plant associations occurring, one above the other, then when one goes up from Veracruz to the plateau of Perote mountain in the space of a few hours, the man of science travels the whole scale of vegetation" (von Humboldt, 1827; Zamudio and Butanda, 1999). During his journey through Mexico, the naturalist Alexander von Humboldt left a record of the diversity of environments that he observed passing through the elevational gradient on the eastern slope of the state of Veracruz in 1803. This gradient begins at the port of Veracruz, on the coast of the Atlantic Ocean (Gulf of Mexico), and extends to the upper parts of the inactive Cofre de Perote volcano (4282 m.a.s.l.). Along a straight line of approximately 81 km, it is possible to travel through four climatic zones (*tierra caliente*, *templada*, *fría*, *helada*), six forest biomes (tropical semideciduous, tropical oak, humid montane, pine-oak, pine, fir forest) and alpine vegetation above timberline (Fig. 1). The presence of these different vegetation types and a high diversity of plant species along the elevational gradient is caused by an environmental heterogeneity defined by the combination of climatic, topographic and edaphic (soil) factors (Stein et al., 2014).

The upper zone of the elevational gradient (above 1500 m) forms part of the Trans-Mexican Volcanic Belt (TMVB). The lower part is formed by small hills extending to the coastal plain of the Gulf and the Sierra de Manuel Díaz. This is a mountain formation located across from the sea originating from pyroclastic flows of the Tertiary (Geissert and Enríquez, 2011). Finally, at sea level, there are the coastal lagoons of "La Mancha-El Llano," which are part of the area designated as "Ramsar" site.

Due to geomorphological conditions, the study area presents a wide variation of climates, (i.e., warm environments in the lower part, temperate in the mid-montane areas and cold in the upper part) (Soto Esparza and Giddings, 2011). Both the temperature and precipitation vary according to elevation (Fig. 1). The temperature shows a linear decrease with increasing elevation, while the average precipitation is higher in the middle parts and decreases at the extremes of the gradient (Carvajal-Hernández et al., 2017).

Numerous studies have been carried out that describe the elevational patterns of various taxonomic groups in different tropical zones of the world (e.g., Rahbek, 1995; Blackburn and Gaston, 1996; Kessler, 2001; Krömer et al., 2005; Grau et al., 2007). These studies have shown that biodiversity can depend either directly or indirectly on elevation. However, little is known about how species richness varies in the transitional zone between the Nearctic and Neotropical regions, as is the case in Mexico, particularly in

Fig. 1 Schematic representation of the types of vegetation and climatic zones present along the elevational gradient of the Cofre de Perote, Veracruz, Mexico (Gómez-Díaz et al., 2018).

the state of Veracruz. Furthermore, very few studies have analyzed the anthropogenic influence in different elevational belts and its impact on biodiversity (Kessler et al., 2001). This last issue is of great importance because currently, anthropic landscapes dominate the surface in Mexico (Sánchez Colón et al., 2009). The state of Veracruz is no exception with a loss of over 90% of its pristine vegetation (Castillo-Campos et al., 2011).

Over the course of 8 years, we have studied the distributional patterns of vascular plant diversity and the underlying abiotic factors in this region. Additionally, we studied the impact of anthropogenic disturbance on floristic diversity. All this has been realized within the framework of the interdisciplinary project entitled “BIOVERA: Exploration and explanation of biodiversity patterns along gradients of altitude, climate and anthropogenic influence in central Veracruz, Mexico.” This article deals with the most relevant aspects of the composition and diversity of the vascular flora present within the vegetation types along the elevational gradient, as well as the environmental problems of the region in which it is immersed. For this, we took ferns, terrestrial herbaceous angiosperms and shrubs as representative examples.

The first plant group includes many taxa associated with conserved environments, and thus ferns are considered as bioindicators of ecosystem quality (Krömer et al., 2013, 2014; Carvajal-Hernández et al., 2014; Armenta-Montero et al., 2015). In contrast, herbaceous plants have been associated with secondary ecosystems (Barlow and Gardner, 2007; Gómez-Díaz et al., 2017a, 2017b). Although no in-depth studies have classified shrubs as bioindicators, Bautista-Bello et al. (2019) have observed an increase in their richness and changes on the floristic composition with human disturbance. But this only happens in warm environments (at elevations lower than 1000). Thus, it is likely that some taxonomic groups could be used as an indicator of human disturbance.

Vegetation Types

The orographic and climatic differences that occur along the transect allow the presence of different types of forest vegetation. These climates range from dry and warm environments in the lower part (tropical semi-humid deciduous forest and tropical oak forest) to humid-temperate zones at mid-elevations (humid montane forest and pine-oak forest), and cold conditions in the upper part (pine forest and fir forest) (Figs. 1 and 2).

Hereinafter, the different vegetation types are described according to our field observations and considering information published by Castillo-Campos et al. (2011), Carvajal-Hernández and Krömer (2015), Gómez-Díaz et al. (2017a, b), and Bautista-Bello (2018).

Fig. 2 Views of vegetation types along the elevational gradient of the Cofre de Perote, Veracruz, Mexico. (A) Tropical semihumid deciduous forest; (B) Tropical oak forest; (C) Humid montane forest; (D) Pine-oak forest; (E) Pine forest; (F) Fir forest.

Tropical semihumid deciduous forest is found from sea level to 800 m in the elevational gradient studied and is represented in fragments isolated by anthropogenic activity. *Bursera simaruba* (L.) Sarg., *Comocladia engleriana* Loes., and *Plumeria rubra* L. stand out in the arboreal stratum (Fig. 2A). Due to the proximity with the transition zone of the tropical oak forest, it is also possible to find individuals of the genus *Quercus*. The shrub layer is dominated by *Dioon edule* Lindl., *Chusquea* Kunth., and some species of *Chamaedorea* Liebm. ex Mart. The herbaceous stratum is dominated by fern species of the genera *Adiantum* L. and *Tectaria* Cav. The hemiepiphytes are also represented by aroids of the genera *Monstera* Adans. and *Philodendron* Schott.

Tropical oak forest is found in the elevational gradient between 900 and 1100 m (Fig. 2B). The most representative species are *Quercus oleoides* Schltdl. and Cham., *Q. peduncularis* Nee and *Q. sapotifolia* Liebm. in combination with some lowland species, such as *Byrsonima crassifolia* (L.) Kunth and *Pouteria campechiana* (Kunth) Baehni. Epiphytic orchids, such as *Brassavola nodosa* (L.) Lindl., *Epidendrum ciliare* L. and *Prosthechea radiata* (Lindl.) W.E. Higgins, also occur together with abundant bromeliads (e.g., *Tillandsia ionantha* Planch., *T. paucifolia* Baker, and *T. filifolia* Schltdl. and Cham.) and lianas (*Smilax regelii* Killip and C.V. Morton). *Acacia cornigera* (L.) Willd., *A. pennatula* (Schltdl. and Cham.) Benth., *Malvaviscus arboreus* Cav., *Erythrina herbacea* L., *Lysiloma acapulcense* (Kunth) Benth., and *Bambusa amplexifolia* (J. Presl) Schult. grow in the shrub layer. In the herbaceous stratum, *Bromelia pinguin* L. and *Blechnum occidentale* L. stand out. This vegetation type is represented in isolated fragments, which are remnants of the Pleistocene of boreal origin that replaced the tropical vegetation during the last glaciations (Arriaga et al., 2000).

Humid montane forest can be found in the study gradient between 1300 and 2200 m of elevation (Fig. 2C). It is characterized by the presence of *Carpinus caroliniana* Walter, *Liquidambar styraciflua* L., *Clethra mexicana* DC., *Meliosma alba* (Schltdl.) Walp., *Styrax glabrescens* Benth., and several species of *Quercus* L., which dominate the arboreal stratum. The most common shrubs are *Psychotria* L. and tree ferns of the genera *Cyathea* Kaulf. and *Alsophila* R.Br. Epiphytic herbs are abundant in this environment with ferns represented by several genera. The families Bromeliaceae and Orchidaceae stand out for their species diversity.

Pine-oak forest occurs between 2300 and 2600 m of elevation (Fig. 2D). *Quercus crassifolia* Bonpl. and *Q. laurina* Bonpl., *Pinus patula* Schltdl. and Cham., and *Taxus globosa* Schltdl. are the species that stand out in the arboreal stratum. The shrub layer is represented mainly by species of the genus *Senecio* L. Species of the Asteraceae and Poaceae dominate the herbaceous stratum along with ferns of the genera *Dryopteris* Adans., *Plagiogyria* Bower, and *Polystichum* Roth.

Pine forest is located at elevations between 2700 and 3000 m and exhibits reduced plant richness (Fig. 2E). The most representative tree species are *Pinus pseudostrobus* Lindl., *P. montezumae* Lamb., and *Arbutus xalapensis* Kunth. In the shrub layer, *Baccharis conferta* Kunth stands out. The herbaceous stratum is mostly represented by species of the Poaceae, Asteraceae, and Crassulaceae, the latter mainly of the genus *Echeveria* DC., as well as ferns of the genus *Dryopteris* Adans. Epiphytism is scarce, represented mostly by two fern species (*Pleopeltis polylepis* (Roem ex Kunze) T. Moore and *Polypodium plebeium* Schltdl. and Cham.)

Fir forest is confined to high mountain sites, between 3100 and 3600 m (Fig. 2F). This plant community is composed of arboreal elements whose height varies between 20 and 40 m. The characteristic feature of its dominant elements is the typical triangular shape of its cups. *Abies religiosa* (Kunth) Schltdl. and Cham. is well represented in the upper part of the Cofre de Perote, where the shrub and herbaceous strata are scarce.

Alpine vegetation occurs in areas above timberline (± 3900 m). It is composed mainly by species of the Poaceae family, which dominate the landscape of this vegetation type. Additionally, some shrub elements such as *Juniperus monticola* Martínez, as well as species of the Berberidaceae and Grossulariaceae can be found. Below that elevation, the arboreal vegetation starts with *Pinus hartwegii* Lindl. trees of low stature.

Distributional Patterns of Vascular Plant Richness Along the Elevational Gradient

The vegetation types present along the elevational gradient are found in isolated fragments immersed in a landscape that is strongly transformed by human activities (e.g., livestock, coffee, mango, and sugarcane plantations). Thus, the area is not exempt from the factors that have led to the sharp decline in the original vegetation of the state of Veracruz (i.e., represented by less than 10% of its original surface across the state) (Castillo-Campos et al., 2011; Ellis et al., 2011). For the study area, it has been shown that the surface of the remaining forests has decreased by 57% with an increase of the deforestation rate from 2000 to 2014 (Gómez-Díaz et al., 2018). This environmental degradation is particularly striking because Veracruz is recognized for its high floristic diversity and for showing a high degree of plant endemism (Gómez-Pompa et al., 2010). The state ranks as having the third highest number of vascular plant species in the country, following Chiapas and Oaxaca (Villaseñor, 2016).

Given the high diversity of environments and species in the study area and considering the evident loss of forest cover, we considered the following research questions:

- Which are the distribution patterns of vascular plants?
- What impact does the anthropogenic disturbance have on plant diversity?

To answer the above questions, we established a method of studying local plant diversity through sampling plots of 400 m^2 (Kessler and Bach, 1999). These plots were distributed in eight different elevational belts from the sea level up to 3500 m, approximately every 500 m in elevation (Fig. 3).

It is important to clarify that, for this study, no plant sampling was realized in the alpine vegetation (above 3900 m) because no forest cover is found here. Thus, comparisons with the rest of the data are not possible. Along this elevational gradient, we sampled ferns, terrestrial herbaceous angiosperms and shrubs in all forest vegetation types, from the tropical forests at the lower part to the coniferous forests at the upper zone of the transect. Furthermore, to study the impact of the anthropogenic disturbance on plant diversity within each elevational belt, we sampled in plots at different habitats: old-growth forest (without evident disturbance), degraded forest (with evident anthropogenic disturbance, for example, selective logging, livestock grazing, firewood collection, roads, etc.) and secondary forest (of about 15 years of regeneration) (Table 1).

Fig. 3 Location of the elevational transect on the eastern slope of the Cofre de Perote, Veracruz, Mexico. (1) La Mancha (20 m); (2) Palmarejo (500 m); (3) Chavarrillo (1000 m); (4) Los Capulines (1500 m); (5) El Zapotal (2000 m); (6) El Encinal (2500 m); (7) Los Pescados (3000 m); (8) El Conejo (3500 m) (Gómez-Díaz et al., 2017a).

Table 1 Classification of habitats with different forest-use intensities according to the main physiognomic characteristic, the gap fraction in the canopy, dominance of canopy trees, percentage of shrubs and the presence of lianas, along the elevational gradient of Cofre de Perote, Veracruz, Mexico

Habitat	Characteristic	Gaps (%)	Forest-use intensity	Canopy trees	Shrub (%)	Lianas
Old-growth	No obvious forest use, dominance of mature trees	<10	Low	High	<30	Very low
Degraded	Selective logging, grazing and understory removal	11–25	Medium	Low	30–50	Low
Secondary	regrown after clear-cut	>25	High	Very low	>50	High

In total, we recorded the presence of all species of ferns (terrestrial and epiphytic), herbaceous angiosperms and shrubs in 120 plots (4800 m²). Additionally, we placed data loggers in each of the six vegetation types present in the region. These loggers recorded the microclimate (temperature, relative humidity, and light incidence) during a full year between 2014 and 2015.

Our results showed a total of 551 vascular plant species (Bautista-Bello et al., 2019; Carvajal-Hernández and Krömer, 2015; Gómez-Díaz et al., 2017a). In Veracruz, there are 8497 vascular plants and in Mexico 23,314 (Villaseñor, 2016), thus the study area represented 6.4% of the State's and 2.3% of the country's flora (Table 2).

The species distribution patterns along the gradient varied according to each group. For example, the highest richness was found at 2000 m for ferns (Carvajal-Hernández and Krömer, 2015) and at 2500 m for terrestrial herbs (Gómez-Díaz et al., 2017a), which both showed a hump-shaped diversity pattern. In contrast, for shrubs, we observed a peak at 1000 m followed by a decrease of species with increasing elevation (Bautista-Bello et al., 2019).

Nevertheless, the highest diversity of ferns and herbs was generally located between 1500 and 2500 m. This area coincides with the presence of humid montane forests, which have been shown to be the habitats with the highest plant diversity per surface area in Mexico (Rzedowski, 1996; Gual-Díaz and Rendón-Correa, 2014). On the other hand, the humid montane forest represents less than 1% of the surface in Mexico, with a decreasing tendency due to its continuous deforestation and fragmentation (CONABIO, 2010; Gual-Díaz and Rendón-Correa, 2014). Taking the ferns as an indicator group of the quality of the ecosystems (Carvajal-Hernández et al., 2014; Krömer et al., 2014), this study corroborated previous findings that the humid montane forest suffers the greatest loss of species richness due to anthropogenic influence. Furthermore, it is necessary to consider that the decrease in fern richness also leads to a loss of ecosystem functions (Carvajal-Hernández et al., 2017, 2018a). This combination of factors makes the humid montane forest the most-affected vegetation type along the studied elevational gradient.

In the elevational range where humid montane forests are found, mean annual temperature ranges between 16°C and 12°C, mean annual precipitation ranges between 1700 and 1800 mm, and relative humidity between 85% and 90% (Carvajal-Hernández et al., 2017). The data loggers placed in the study area showed that temperature and relative humidity values decreased uniformly with increasing elevation. However, anthropogenic disturbance led to an increase in temperature and incidence of light in the microclimate, which caused a decrease in relative humidity. Although it is true that this phenomenon occurs in all the elevational belts studied, these changes were more accentuated in the humid montane forest (Carvajal-Hernández et al., 2017).

Another factor that must be highlighted is that both elevations of 1000 m and 2500 m (where shrubs and terrestrial herbs, respectively, are most diverse) correspond to transitional sites between different vegetation types (Fig. 1). This suggests that these are areas where the confluence of mainly climatic factors allows a mixture of species coming from areas around the transition sites and increases the diversity of these groups (Heaney, 2001; De León-Mata et al., 2013; Llambi, 2015).

The temperate pine and fir forests of the upper zone of the elevational gradient, as well as the vegetation types of the lower zones, presented the lowest diversity of all study groups (Fig. 1 and Table 2). We attributed this to several factors. For example, ferns have less beta and functional diversity related to the changes in species composition when a disturbance occurs. Therefore, the species

Table 2 Species richness of the groups studied along the elevational gradient of Cofre de Perote, Veracruz, Mexico (Bautista-Bello et al., 2019; Carvajal-Hernández and Krömer, 2015; Gómez-Díaz et al., 2017a)

Elevation (m)	Vegetation type	OG			DE			SE			Total species richness

Type of vegetation: TSDF: tropical semideciduous forest, TOF: tropical oak forest, HMF: humid montane forest, POF: pine-oak forest, PF: pine forest, and FF: fir forest. OG: old-growth; DE: degraded forest; SE: secondary forest. F: Ferns; H: Herbs; S: Shrubs.

that occur at the extremes of the gradient are specifically adapted to the stressful conditions of that extreme (i.e., high temperatures and prolonged droughts in the lower zones and low temperatures, winter snowfall, and summer droughts in the upper zones).

The above indicates that conditions of relative climatic stability prevail in the middle part of the elevational gradient. This is an important factor in establishing a higher number of species due to the existence of favorable circumstances for the diversification of niches, following the arguments that explain the higher diversity observed in the tropics (Hildebrand, 2004). In contrast, this situation does not occur at the extremes of the gradient, where climatic heterogeneity exerts a strong pressure on diversity, limiting the presence of species to those with the capacity to adapt to these mostly unfavorable conditions.

Anthropogenic Impact on Species Richness

We observed that the anthropogenic disturbance had different impacts on species richness depending on the plant group. For example, in the case of ferns, disturbance generated a loss of species, while a higher richness of herbs was observed in the zones with moderate forest-use intensity (Table 3).

Ferns have been used as a study group to understand the patterns of species richness worldwide for two main reasons. First, they are widely distributed on the planet with approximately 11,000 species (PPG, 2016). Second, due to their reproduction by spores, the dispersion of the species is highly dependent on environmental conditions such as temperature, humidity, and the substrate. This minimizes their dependence on biotic factors. These features have also resulted in their use as bioindicators of ecosystem quality (Carvajal-Hernández et al., 2017).

In contrast, little is known about the influence of human disturbance on herbaceous angiosperms, despite their importance for tropical diversity and ecosystem function (Willinghöfer et al., 2012; Cicuzza et al., 2013). Studies published thus far indicate that many primary and endemic forest herbaceous species were also recorded in areas with secondary vegetation (Barlow et al., 2007). Therefore, such anthropic habitats could help to conserve endemic species (Marin-Spiotta et al., 2007).

Furthermore, particularly little is known about the human impact on the diversity and distribution of shrubs. The few studies that consider shrub species suggest that disturbance and fragmentation affect the seeds and seedlings of the understory in lowland forests by modifying microclimatic conditions in a fragmented landscape. Apparently, this group is adapted to moderate conditions of humidity and temperature that, respectively, decrease and increase with the intensity of forest-use (e.g., Dale et al., 2001; Leicht-Young and Pavlovic, 2015; Schnitzer, 2015).

Our sampling method (described in the previous section) revealed that ferns were sensitive to changes in the microclimate caused by disturbance, whereas herbaceous plants exhibited no influence from disturbance. For shrubs, we observed that changes in forest structure caused by human action can increase the total richness within the forest fragments. However, their floristic composition was modified due to a loss of species of 7%–26% when changing from an old-growth forest to a secondary one (Tables 2 and 3).

Modifications in the structure of the humid montane forests caused by human action considerably affected fern communities, as evidenced by a 40% to 70% reduction in species richness in disturbed vegetation (Carvajal-Hernández et al., 2017) (Table 3). This reduction was largely due to changes in the microclimate and forest physiognomy (Köster et al., 2009). In the elevational belts of 1000 and 3500 m, the secondary forests harbored the same richness as the old-growth forests due to the presence of species adapted to extreme conditions of drought and temperature, which are not affected by the disturbance (Hietz, 2010). The richness of 155 ferns found in this study represent 27% of the 574-species recorded for Veracruz (Krömer et al., 2015; Carvajal-Hernández et al., 2018b) and 15% of the 1030 Mexican pteridophytes (Tejero-Díez et al., 2014). However, only three of these 155 are endemic to Mexico and nine are protected by Mexican law (NOM-059-SEMARNAT-2010) for presenting some status of extinction risk. Considering that this richness was registered in a small sample area (4800 m²), the elevational gradient studied protects an important proportion of the country's pteridophyte flora. The epiphytic component of the ferns represented almost 50% of the total richness, however, its proportion changed according to elevation (Carvajal-Hernández and Krömer, 2015).

The influence of disturbance on ferns was not only observed in terms of richness but also in terms of species turnover. We observed a strong exchange of species between an old-growth forest and disturbed sites, as well as a loss in functional diversity (mainly in the humid montane forest). However, at 500 m richness decreased, but functional diversity remained constant, indicating functional redundancy in that environment (Carvajal-Hernández et al., 2017, 2018a).

Regarding herbaceous angiosperms, we recorded 264 species of which 31 are endemic to Mexico (Gómez-Díaz et al., 2017a). Both alpha and gamma diversity showed a hump-shaped pattern with a peak of richness between 2500 and 3000 m, respectively.

Table 3 Species richness by plant group and by environment/habitat (OG: old-growth; DE: degraded; SE: secondary forest) reported along the elevational gradient of Cofre de Perote, Veracruz, Mexico

Group	Total	OG	DE	SE	Elevation (m) with a peak of species richness
Shrubs	132	111	111	115	1000
Ferns (terrestrial and epiphytes)	155	161	119	114	2000
Terrestrial angiosperm herbs	250	145	173	163	2500
Total	551	417	403	392	

We inferred that the belt of 2500 m is particularly sensitive to anthropogenic disturbance and intensification of forest-use. At 3100 m, a high total diversity (50 species) was driven by a high beta diversity within the habitats (Table 2). Here, a loss of a specific forest area could be compensated if similar assemblages are produced in nearby areas. High beta diversity and endemism suggested that mixtures of different habitats are needed to maintain a high gamma diversity of terrestrial herbs along the elevational gradient. In general terms, the disturbance does not affect the species richness, as indicated by the fact that the values of alpha diversity remained constant with disturbance. However, the beta diversity was observed to be higher when comparing mature forest with secondary forest.

Regarding shrubs, we recorded a total of 118 species and 14 morphospecies (a taxonomic species based wholly on morphological differences from related species and that its identity has not been possible due to the lack of any element of taxonomic importance) (Bautista-Bello et al., 2019). Forest fragments in the elevational belts of 500 and 1000 m are the most species-rich but are at the same time the most susceptible to human disturbances. The anthropogenic influence on these forests can increase the diversity of species locally, but also modify the floristic composition of an old-growth habitat when transformed to a secondary one. Furthermore, there were six endemic species to Mexico and one under protection (*Oreopanax echinops* (Schltdl. and Cham.) Decne. and Planch.) according to the IUCN Red List of threatened species. The conservation of these species represents an important topic considering the scarce floristic and ecological information on this and other plant groups.

It is important to mention that no shrub species registered in this study appears in the NOM-059-SEMARNAT-2010 (SEMARNAT, 2010), which protects native species of flora and fauna in Mexico. Nevertheless, the list of plants included in the NOM is incomplete or outdated, and thus the number of endangered shrub species in the area is uncertain. There are new, rare or endemic species like *Hoffmannia arqueonervosa* Cast.-Campos and *Psychotria perotensis* Cast.-Campos (Castillo-Campos et al., 2009, 2013), which have recently been discovered in fragments near the study gradient which should be considered as threatened. Likewise, there are species from other groups of plants that are endemic to the central region of Veracruz, such as *Monstera florescanoana* Croat, T. Krömer and Acebey, *Peperomia chazaroi* G. Mathieu and T. Krömer and *Resinanthus aromaticus* (Cast.-Campos and Lorence) Borhidi (Croat et al., 2010; Gómez-Pompa et al., 2010; Mathieu et al., 2015), and which are endangered due to the reduction of their populations and anthropic pressure exerted on the plant communities where they occur. Therefore, it is important to study the ecological patterns of all plant groups as these are not distributed following a general pattern but respond differently to biotic and abiotic factors (Tables 2 and 3).

General Conclusions

The elevational gradient studied traverses six different forest biomes between sea level and the upper slopes of the Cofre de Perote mountain, which represent a considerable part of the species richness of the vascular flora of the state of Veracruz and Mexico. This high diversity of vegetation types and plant species is a result of varying climatic and topographic conditions that occur along the mountain range (Figs. 1 and 3). In general terms, although it depends on the plant group, the diversity of species is concentrated in the middle part of the gradient, in the humid montane forest, or in the adjacent transition zones. In the cases of terrestrial and epiphytic ferns and terrestrial herbs, the highest diversity was found in mid-elevations between 2000 and 2500 m. In the case of shrubs, the richness peak was found generally in areas between 500 and 1000 m. Both extremes of the elevational gradient present contrasting climatic conditions in different periods of the year (prolonged droughts and extreme temperatures) that limit the presence of a high diversity of species of the studied plant groups (Table 3).

The forest cover in the study area has been constantly reduced for the implementation of livestock and agricultural land. Based on several recent studies, it is known that the region harbors an important part of the state's plant diversity. However, a large portion of the flora is affected by anthropogenic disturbance, and thus it is necessary to establish conservation plans for the area that include interconnected fragments to allow the dispersal of species. This will ensure the conservation of the high plant diversity, as well as of other organisms that depend on the vegetation, still found in the montane region of eastern Mexico.

Glossary

Biogeoclimatic ecosystem classification system (BEC) An ecosystem-based classification system that groups ecologically similar sites based on climate, vegetation, soils, and topography. BEC is widely used throughout British Columbia as a framework for resource management and scientific research.

Canopy veteran A tree of advanced age which dominates the upper canopy of a forest. Veteran trees often provide important microhabitats such as cavities, bare wood and dead branches that support birds and mammals and tree-dwelling lichens, mosses and liverworts.

Climate envelope The specific temperatures and rainfall patterns associated with the locations where a particular species currently exists. Climate envelope models are used to predict the hypothetical distribution of species under various future climate change scenarios.

Climatic moisture deficit An index of moisture availability, reflecting the degree to which monthly evapotranspiration demand of local vegetation is exceeded (or met) by monthly precipitation. A deficit represents the amount of moisture plants must capture from other sources (fog, ground water, etc.).

Coarse woody debris (CWD) Fallen dead trees and the remains of large branches on the ground in forests. Standing and dead fallen trees are a critical component of forested ecosystems and contribute to nutrient cycling, long-term carbon storage, tree regeneration, wildlife habitat, and biological diversity. CWD is defined as having a cross-sectional diameter of ≥ 10 cm.

Cumulative environmental impact Changes to the environment (both physical and ecological) caused by multiple past and present human actions. Cumulative impacts are often difficult to predict.

Decadent forest A term applied by the logging industry to forests containing dead, broken, deformed, or very old trees. Such forests are ecologically among the most valuable because they sustain a disproportionately high number of biological processes and living species (biodiversity).

Edge effects Changes in population or community structure (the number and type of organisms that are present) caused by an abrupt transition between two quite different adjoining habitats. Edge effects commonly result in the loss of forest dependent species after forests have been fragmented by roads and logging.

Gap dynamics A common process of tree growth in mature and old-growth forests whereby the death of one or a few large dominant trees permits smaller trees within the forest understory to grow and fill their place.

Old-growth Management Area (OGMA) In British Columbia, a spatially defined area of (ostensibly) old-growth forest where logging and other forestry development is discouraged or constrained in order to achieve biodiversity targets; but see Fig. 12.

Orographic rain Precipitation produced when moist air is lifted, cools, and forms clouds as it moves over a mountain range.

Rain shadow An area with relatively little precipitation due to the effect of a topographic barrier, usually a mountain range, which causes the prevailing winds to release their moisture on the windward side, causing the leeward side to be dry.

Silvicultural system Techniques used to control the establishment, growth, composition, and quality of forest vegetation for a specific suite of forest resource objectives. Activities may include planting, brushing, spacing, thinning, fertilizing, and application of herbicides.

Subboreal A biogeographic zone that approaches the boreal in climatic condition but is neither as cold nor as dry.

Toe-slope A topographic position where the lower slopes of a U-shaped valley meet the flat valley bottom.

Abstract

The Inland Temperate Rainforests (ITR) of Northwest North America represent a globally significant biome characterized by a unique assemblage of oceanic and boreal taxa. Here we recognize two major ITR ecosystems in British Columbia, both of which were historically dominated by old-growth forests: (1) the Kispiox ITR in the rain shadow of the North Coast Mountains; and (2) the Caribou ITR on the windward side of the North Columbia Mountains. A third major biome, the Interior Wetbelt, stretches southward from the Caribou ITR into Montana, Idaho, and Washington State. The Interior Wetbelt contains topographically induced pockets of rainforest, but is characterized by a more open mosaic of forests and grassland. The loss of old-growth forests in ITR ecosystems, primarily due to logging, has now reached critical thresholds. Only 31.7% and 23.1% respectively of Kispiox and Caribou ITR landscapes remain as old-growth forests, with the Interior Wetbelt down to 4.6% old-growth forest. This poses major threats to old-growth-dependent taxa such as the critically endangered deep-snow mountain caribou. We recommend an immediate moratorium on clear-cut logging in forest stands older than 250 years within the Kispiox and Caribou ITR. Given the extreme rarity of old-growth forests in the Interior Wetbelt, remaining stands exceeding 150 years in age should be designated as protected areas. Management plans in all three regions should include measures to ensure that remnant old-growth forest stands are buffered from the adverse impacts of adjacent cut-blocks. This should be accompanied by the development of landscape-level conservation designs, recognizing the needs for connectivity and continuity of old-growth forest cover.

What is the Inland Temperate Rainforest?

The Coastal Temperate Rainforest (CTR) biome is characteristic of mid-latitude maritime regions, where coastal mountain ranges causes onshore winds to release much of their moisture as rain or snow before heading inland (DellaSala et al., 2011a). In the northern hemisphere, CTRs are restricted primarily to the western and eastern margins of North America and Eurasia, where they are defined by their mild maritime climate, moderate seasonal temperatures, and significant precipitation spread more or less evenly over the year (Alaback, 1996; DellaSala et al., 2011a). The most extensive such forests occur along the Pacific coast of North America, stretching >2500 km from southeast Alaska in the north, through British Columbia (B.C.), and southward into northern California (Fig. 1).

Also present in western North America, Europe and Asia are inland variants of the temperate rainforest biome. Such ecosystems, variously termed Inland Temperate Rainforests and Inland Per-humid Rainforests (Goward and Arsenault, 2000; Stevenson et al., 2011; DellaSala et al., 2011b,c), occur exclusively in the Northern Hemisphere and are much more circumscribed than their coastal counterparts (DellaSala et al., 2011a). In this article we characterize three Inland Temperate Rainforest (ITR) ecosystems that have been recognized in western North America, here referred to as the Kispiox ITR, the Caribou ITR and the Interior Wetbelt (Fig. 1).

Unlike the Pacific CTR, which forms a broad continuous band along the west coast of the continent (Fig. 1), ITR ecosystems in western North America are generally constrained within mountain valleys, making them more linear and essentially discontinuous. This is especially the case with the Interior Wetbelt, where forest stands with ITR characteristics are generally confined to small areas such as mesic canyons and the spray zones of waterfalls (McCune and Allen, 1984; Goward and Spribille, 2005).

The Kispiox Inland Temperate Rainforest

The Kispiox ITR occurs between ca. 55° N and 56° N in the immediate rain shadow of the Coast Mountains in the Skeena and Nass River watersheds (Fig. 1). Transitional to the Pacific CTR, its forests are classified within the Interior Cedar-Hemlock (ICH) biogeoclimatic (BEC) zone of Meidinger and Pojar (1991). Included here are both the wetter and cooler “Wet Cold” and “Very-Wet Cold” ICH BEC subzones of the Iskut and Nass River watersheds, and the somewhat drier and warmer “Moist Cold” ICH BEC subzone of the upper Skeena watershed (Fig. 1).

Reflecting its transitional status, the Kispiox ITR supports a mix of both coastal temperate rainforest trees, such as amabilis fir (*Abies amabilis*), and Roche spruce (*Picea glauca* × *sitchensis*), and subcontinental trees, such as hybrid spruce (*Picea engelmannii* × *glauca*) and subalpine fir (*Abies lasiocarpa*). The climate of the Kispiox ITR is strongly influenced by colder and drier continental air masses that periodically occupy B.C.’s central-interior plateau, with proportionately more winter precipitation occurring as snow than in coastal locations (Fig. 2). Predicted mean annual precipitation at Date Creek in the Kispiox River watershed (Fig. 1) is 801 mm (Fig. 2), well below the predicted annual total (2694 mm) at Butze Rapids (Fig. 1) in the Pacific CTR (Fig. 2). Importantly, this difference in absolute precipitation is partly compensated for by the relatively low climatic moisture deficit (mm) during the growing season (64 mm total; from Wang et al., 2012), a function of relatively wet, cool summers (Fig. 2) and shelter from wind.

The Caribou Inland Temperate Rainforests

The Caribou ITR occurs between ca. 50° 30' and 54° N along the windward slopes of the Columbia and Rocky Mountains, where the upper Fraser River and upper Columbia River watersheds overlap with the “Wet” and “Very Wet” subzones of ICH BEC zone (Fig. 1). Climatically, these landscapes are characterized by long snowy winters and cool wet summers. At the Ancient Forest Trail

Fig. 1 Distribution of the Pacific Coastal and Inland Temperate Rainforest (CTR and ITR respectively) and Interior Wetbelt ecosystems in western North America. CTR distribution is indicated in British Columbia by the distribution of the Coastal Western Hemlock (CWH) biogeoclimatic (BEC) zone (after Meidinger, D and J Pojar. (1991). *Ecosystems of British Columbia*. British Columbia Ministry of Forests, Special Report Series 6: 1–330, British Columbia Victoria. <https://www.for.gov.bc.ca/hfd/pubs/docs/srs/srs06.htm>), and in the United States (Alaska, Washington, and Oregon) by the occurrence of western hemlock (*Tsuga heterophylla*) (from Data Basin, Wilberforce Foundation). The Kispiox ITR is indicated by the combined “Very Wet Cold,” “Wet Cold,” and “Moist Cold” Interior Cedar Hemlock (ICH) BEC subzones in the upper Skeena and Nass River watersheds. The Caribou ITR is indicated by the combined “Wet” and “Very Wet” ICH BEC subzones in the headwaters of the Fraser and Columbia River watersheds. Interior Wetbelt is indicated by the “Moist” ICH BEC zone in the B.C. interior, and by the occurrence of western hemlock in comparable ecosystems southward into Washington State, Idaho, and Montana. The number of “rainforest” lichen indicator species (oceanic lichens) is shown for coastal and inland locations within a $1 \times 1^\circ$ longitude-latitude grid (adapted from Goward, T, and T. Spribille. (2005). Lichenological evidence for the recognition of inland rain forests in western North America. *Journal of Biogeography* 32: 1209–1219. 10.1111/j.1365-2699.2005.01282.x). The location of reference climate data sites (see Fig. 2) is indicated by place name labels.

Fig. 2 Predicted climate variables (mean annual precipitation—MAP, mean annual temperature—MAT, mean monthly temperature, mean monthly precipitation as snow, and mean monthly precipitation as rain) for Coastal Temperate Rainforest (CTR) sites at Butze Rapids near Prince Rupert (Butze), Calvert Island (Calvert) on the British Columbia central-coast, and Vargas Island (Vargas) off southern Vancouver Island; for the Kispiox Inland Temperate Rainforest (ITR) at Date Creek (Kispiox); for the Caribou ITR sites at the Ancient Forest Trail (ITR), and Giant Cedar's Trail (ITR); and for the Interior Wetbelt (IW) at West Arm Park. See Fig. 1 for location of sites. Climate data estimated for the historical period (1961–90) using Climate BC—ClimateWNA version 6.00 (Wang et al., 2012). Note that the range for plotted precipitation estimates is greater for CTR (up to 525 mm) than for the ITR and IW sites on the right (up to 175 mm).

site in the headwaters of the Fraser River watershed (Fig. 1), for example, about 40% of total annual precipitation (1054 mm) falls as snow, while the average mean temperature for June–July–August is only 13.3 °C (Fig. 2). Our choice of the name “Caribou ITR” reflects the findings of Apps and McLellan (2006), who emphasize a high degree of correspondence between the areal extent of these ICH BEC subzones and the probability of long-term persistence by the deep-snow mountain caribou (*Rangifer tarandus caribou*) (see also Moskowitz, 2018).

Historically, the Caribou ITR was dominated by old-growth forest cover, with western redcedar and western hemlock present over a wide range of site series (Radies et al., 2009). DeLong (1998) estimated that the natural range of variability for old-growth forest (> 140 years) cover in “wet-trench” forests of the upper Fraser River valley was between 76% and 84%. Stand structure in the Caribou ITR has correspondingly been shaped mainly by processes of gap dynamics, where new trees establish in openings

created by the death of canopy veterans (Lertzman et al., 1996). Foresters have often characterized old-growth forest in the Caribou ITR as “decadent,” on the assumption that such stands are near the end of their life, unable to sustain themselves over time (see quotes in Chapter 5, Stevenson et al., 2011). In work on Vancouver Island, however, Daniels (2003) notes that old and very-old CWR stands need relatively few regenerating trees to maintain stand structure under processes of gap dynamics, a finding that would apply equally to old Caribou ITR forests.

Although processes of stand regeneration and stand structure share many similarities between the Pacific CTR and Caribou ITR (Goward and Arsenault, 2000), the climate of these two regions differs significantly. Predicted mean annual precipitation (MAP) at the Giant Cedars Trail site in the upper Columbia River watershed (Fig. 1), for instance, is 953 mm (Fig. 2), well below Alaback's (1996) estimated threshold of 1400 mm MAP required for designation of coastal forests as temperate rainforest ecosystems. As noted by DellaSala et al. (2011a,b), however, more recent modeling suggests that MAP thresholds for temperate and boreal rainforest designations are highly influenced by site specific and regional factors. These models suggested that ITR development is possible at MAP values as low as 846 mm (DellaSala et al., 2011a), especially at the northern limit of the ITR, where melt from winter snowpack coupled with elevated early-summer precipitation mitigates evapotranspiration demands on rainforest trees (Gavin and Hu, 2006; DellaSala et al., 2011b). This is particularly relevant to the Caribou ITR, where discharge from deep winter snows (see Figs. 2 and 3) sustains numerous springs and seepage areas on middle and lower hillslopes (Déry et al., 2014). The resultant wet soils create conditions of high ambient humidity and at the same time buffer trees from summer drought (Fig. 4). Konchalski (2014), for instance, found that growth rings of western redcedar do not show a dry-season signal associated with summer precipitation patterns.

The higher canopy humidity in wet “toe-slope” positions also limits the spread of fire after lightning strikes. Individual trees hit by lightning typically burn without spreading into the surrounding stand. Evidence from Sanborn et al. (2006) suggests that fire return intervals in wet “toe-slope” positions may reach 1600 years, while Gavin et al. (2009) reported sites that showed no evidence of wildfire in the two to three millennia since the arrival of redcedar into this portion of its range. The exceptional age and stature attained by such stands (Fig. 4) led Goward (1994) to argue for recognition for “antique” or multigenerational stands, in which the age of the forest exceeds the age of the oldest trees within it. Importantly, protection from stand-level wildfires does not extend to adjacent mid-slope stands growing on steeper terrain and typically dominated by western hemlock (Fig. 5); though even here stands can exceed 250 years in age, with many reaching 400–600 years (Coxson pers. obs.).

Fig. 3 Deep winter snow plays important roles in Inland Temperate Rainforests, preventing frost from penetrating into the ground and protecting shrubs, herbs and soil biota from extreme winter cold. Melt of the winter snowpack is vital for groundwater recharge, sustaining springs and seepage areas that support ancient cedar stands. Image shows late winter snowpack in an “antique” western redcedar (*Thuja plicata*) stand in the Ancient Forest/Chun T’oh Whudujut Provincial Park in the Caribou ITR. Such forests can greatly predate the age of the oldest trees within them.

Fig. 4 Stands of ancient western redcedar (*Thuja plicata*) trees are well developed in the lower “toe-slope” topographic position of the upper Fraser River watershed, shown here at the “Radies” tree along the Ancient Forest Trail in the Ancient Forest/Chun T’oh Whudujut Provincial Park in the Caribou ITR (see Fig. 1 for location). Well developed “buttress” roots are a notable feature of the ancient cedar trees at this location, likely indicating that the water table is close to the surface. Photograph courtesy of UNBC.

Fig. 5 Old western hemlock (*Tsuga heterophylla*) stands dominate rocky mid-slope positions in the upper Fraser River watershed (Caribou ITR), in sites where stand-destroying events such as fire typically occur every 200–500 years. This stands in marked contrast to the very-old “Antique” or “Ancient” cedar stands found in the wet “toe-slope” topographic positions (see Figs. 3 and 4).

The Interior Wetbelt

The third stronghold of inland rainforests is the Interior Wetbelt (Fig. 1). Whereas this term is generally applied to the ICH as a whole, here we adopt it in a more restricted sense. Extending southward from about 50° N in British Columbia to 46° N in northern Montana, Idaho, and Washington, the Interior Wetbelt corresponds mostly to the “Moist-Warm” subzone of the ICH, a region much drier and warmer than the Kispiox and Caribou ITRs. By way of comparison, the predicted summer moisture deficit (mm) for the Ancient Forest Trail site (Caribou ITR; see Figs. 1 and 2) is 53 mm, compared to 186 mm at West Arm Park (Interior Wetbelt) (Fig. 2) (Wang et al., 2012). Reflecting these drier conditions, forest cover in the Interior Wetbelt is typically not continuous over a full range of site series, with drier sites often supporting shrub-dominated or even grassland communities.

Western redcedar and western hemlock, although widely present in the Interior Wetbelt (Fig. 1), are typically restricted to wetter sites, especially where sheltered from frequent wildfire. Arno and Davis (1980) describe fire return intervals of < 150 years for these trees in Northern Idaho, while McCune and Allen (1984) note that stands with western redcedar trees occur only where protected from fire by deep canyons in the Bitterroot Range of western Montana. Gavin and Hu (2006) note that the range of western hemlock in the region covered by the Caribou ITR and Interior Wetbelt is far smaller than would be predicted by examination of the climate envelope for western hemlock in Coastal Temperate Rainforests, a disparity they attribute to the limited time for dispersal since the ITR biome emerged.

Related Ecosystems

We do not include in our treatment of Inland Temperate Rainforests the perhumid forests of the “Very Wet” Sub-Boreal Spruce BEC subzone, which extend northward from the Caribou ITR into the Peace River watershed (Meidinger and Pojar, 1991). These forests have previously been treated as a northern extension of the interior wetbelt (Stevenson et al., 2011), and support many of the same large faunal elements, such as grizzly bear (*Ursus arctos*), wolves (*Canis lupus*) and, in part, deep-snow mountain caribou. However, because they contain few of the oceanic biota which characterize ITR and Interior Wetbelt ecosystems to the south (Goward and Spribille, 2005), we prefer to regard them as boreal rather than temperate (see also Cannings and Cannings, 2015); further work is needed.

Biota of the Inland Rainforest

ITR and Interior Wetbelt forests support 376 wildlife species, including 8 amphibians, 7 reptiles, 293 birds, and 68 mammals (BC CDC, 2019). Among this last group is a full complement of large and small forest carnivores, including grizzly bear, black bear (*U. americanus*), wolf, wolverine (*Gulo gulo*), fisher (*Pekania pennanti*), marten (*Martes americana*), lynx (*Lynx canadensis*), and cougar (*Felis concolor*). Long-term viability for all these species requires large tracts of suitable habitat. Also found throughout the Caribou ITR are at-risk stocks of coho (*Oncorhynchus kisutch*), sockeye (*O. nerka*), and chinook salmon (*O. tshawytscha*) as well as bull trout (*Salvelinus confluentus*) (BC CDC, 2019).

Among the many animals that depend on old-growth ITR forests, the endangered “deep-snow mountain caribou” is certainly the most iconic (Seip and McLellan, 2008). Behaviorally adapted for survival in mountainous regions of deep snow, these caribou walk atop the winter snowpack in search of canopy hair lichens (mostly *Bryoria*), their primary winter forage. Not only are deep-snow caribou endemic to B.C. (see below), they also depend on extensive tracts of old-growth forests both for sufficient winter forage (Goward, 1998) and as a buffer against predation (Wittmer et al., 2005). Past conservation strategies for mountain caribou have focused mainly on protection of high-elevation winter ranges, leaving animals highly vulnerable to predation, as well as to loss of habitat when they venture into adjacent valley-bottom old-growth ITR forests (Kinley et al., 2007) (Fig. 6). This has resulted in steep population declines for most of the Caribou ITR and Interior Wetbelt herds (Fig. 7), with the latter now under imminent threat of extirpation (SARA, 2018). In early 2019, the remaining animals in the Purcell South and South Selkirk herds were captured and relocated to penning areas, bringing about the functional extirpation of free-ranging mountain caribou herds across the U.S.-Canada border (Cox, 2019).

A major indicator group for sites with high conservation value in the CTR and ITR alike is canopy macrolichens. Goward and Spribille (2005) used tree-dwelling macrolichens to assess the degree of environmental congruence between the Inland and Coastal Temperate Rainforest biomes. They showed that about 70% of oceanic species disjunct from the Pacific CTR are restricted within the ITR to regions north of 51° N, with relatively few extending southward into the Interior Wetbelt (Fig. 1). Correlated with this southward decrease in “oceanic” lichens, they noted a parallel decrease in summer precipitation (compare the 81 mm July precipitation at the Ancient Forest Trail site with 48 mm at West Arm Park in the southern B.C. interior; Fig. 2), albeit not with mean annual precipitation. Goward and Spribille (2005) concluded that the ITR is optimally developed between 54° N and 50° N; however, they noted that ITR features occur in a subset of locations further south, for instance, in waterfall spray zones. The importance of spray zones can be seen in preliminary studies conducted at Dawson Falls in Wells Gray Provincial Park, where > 470 lichen species have been recorded, including a high representation of oceanic species (Bjork pers. comm.) (Fig. 8). The total lichen flora of the Wells Gray Park and vicinity is expected to exceed 1000 species (Goward and Björk, 2013), a globally significant lichen assemblage, consistent with habitat values of the Caribou ITR.

Fig. 6 “Deep-Snow” mountain caribou are particularly vulnerable to loss of old-growth forest habitat and increased predation when they descend in the spring (shown here) and fall to forage in valley-bottom ITR stands and to migrate between different local mountain ranges.

Fig. 7 Trends in mountain caribou abundance for selected herds in the Caribou ITR (Central Selkirk, Columbia, Groundhog, Narrow Lake, South Selkirk) and Interior Wetbelt (Purcells South). Adapted from British Columbia provincial government status reports (<https://www2.gov.bc.ca/gov/content/environment/plants-animals-ecosystems/wildlife/wildlife-conservation/caribou>).

Inland Rainforests and Carbon Sequestration

An important ecological and biophysical attribute of ITR stands is their role in carbon sequestration. This is particularly true for the Kispiox and Caribou ITR, where extended intervals between stand-level fires favors accumulation of significant biomass in standing stems (Fig. 4), coarse woody debris (Fig. 9), and forest soils. Matsuzaki et al. (2013) found that total forest carbon stocks in old-growth ITR stands averaged $455 \pm 156 \text{ Mg C ha}^{-1}$, close to that of Pacific CTR (Fig. 10). After clear-cutting, carbon stocks in the ITR stands measured by Matsuzaki et al. were reduced by > 70%—a not insignificant contributor to greenhouse gas emissions. Plantation stands will take many centuries to re-sequester this carbon lost at harvest, especially in wet ITR and CTR stands. Partial-cutting silvicultural systems seemed to provide the best alternative among the logging treatments examined by Matsuzaki et al. (2013), with group-selection logging retaining a high-proportion of the previously sequestered carbon (Fig. 10).

Fig. 8 Waterfall spray zones like this one at Dawson Falls in Wells Gray Provincial Park (Caribou ITR), can provide enhanced ITR characteristics for oceanic lichen and vascular communities in adjacent forests. Photograph courtesy of J. Hollinger.

Fig. 9 Large coarse woody debris, including fallen trees and snags, contributes to high rates of carbon sequestration in old and very-old (“antique”) stands of the Caribou Inland Temperate Rainforest, estimated at over 500 t/ha in the upper Fraser River watershed. Image from the Ancient Forest Trail in Ancient Forest/Chun T’oh Whudujut Provincial Park.

Fig. 10 Total carbon sequestration in Caribou Inland Temperate Rainforest stands after clear-cut logging (IR-CC), group-retention logging (IR-GR), and uncut old-growth forest (IR-OF), compared to logged Coastal Temperate Rainforest stands on Vancouver Island (CR BC—CC), and old-growth Coastal Temperate Rainforests from Vancouver Island (CR BC—OF), Washington State (CR WA—OF), and Oregon (CR ORE—OF). Source data Matsuzaki et al. (2013) for Inland Temperate Rainforest, Trofymow et al. (2008) for Coastal Temperate Rainforest stands on Vancouver Island, and Smithwick et al. (2002) for Coastal Temperate Rainforest stands in Washington State and Oregon.

History and Use of the Inland Rainforest and Interior Wetbelt

After thousands of years of habitation by indigenous peoples—the Lheidli T'enneh, Simpcw, Sinixt, Gitxsan, Nisga'a, Tahltan, and Wet'suwet'en,—colonial settlement in the 19th century and railway construction in the early 20th century brought about major changes in the utilization of the ITR for resource extraction, with logging of redcedar for shakes and poles, and conversion of valley-bottom lands for agriculture (Stevenson et al., 2011) (Fig. 11). Such activities, though widespread, occurred at relatively low intensity until the introduction of clear-cut logging in the 1960s.

Fig. 11 The Rocky Mountain Trench is a major physiographic feature of the Inland Temperate Rainforest and Interior Wetbelt, separating the older Columbia Mountains (seen in distance) from the younger Rocky Mountains. View is south from McBride Peak, showing past development of agricultural lands within the Caribou ITR.

Table 1 Conservation status of the Kispiox and Caribou Inland Temperate Rainforests (ITR) and the British Columbia (B.C.) portion of the Interior Wetbelt.

Region	BEC zone type	Total area (ha)	Road density (km/km ²)	% Cut-blocks ^a	% Young to mid-seral ^b	% Old ^a	% Old in OGMAs ^c	% Old in Parks ^c
Kispiox ITR	Wet	795,544	0.36	20.2	49.2	30.6	4.6	< 0.1
	Moist	277,095	0.84	12.3	52.8	34.9	10.3	9.6
	All	1,072,639	0.72	18.1	50.2	31.7	8.7	6.9
Caribou ITR	Wet	1,312,164.4	0.99	23.0	53.9	23.1	21.3	25.3
Interior Wetbelt	Moist	1,857,832.5	1.37	29.5	65.9	4.6	29.2	22.4
	All	3,169,996.9	1.09	26.8	61.0	12.2	23.0	24.6

Biogeoclimatic (BEC) zones used within each region are the: Kispiox ITR (Wet = combined “Very Wet Cold” and “Wet Cold” ICH; Moist = the “Moist Cold” ICH); Caribou ITR (Wet = “Wet” and “Very Wet” ICH); Interior Wetbelt (Moist = combined “Moist Cool,” “Moist Mild,” and “Moist Warm” ICH BEC zones). Parks includes both provincial and national parks, while OGMAs refer to spatially defined Old Growth Management Areas. Cut blocks includes all past clear-cuts identified within the BC Government database. Old-growth forests are stands >250 years. Young to mid-seral stands denotes the remaining forested land base (not a cut block or old-growth forest), including areas previously burned by wildfires. Data source: British Columbia Data Catalogue^d (<https://data.gov.bc.ca/>), accessed September 2, 2018.

^aExpressed as percentage of landscape (ha) in this BEC subzone.

^bGIS Spatial Layers used: Forest cover inventory (WHSE_FOREST_VEGETATION.VEG_COMP_LYR_L1_POLY); BEC classification

(WHSE_FOREST_VEGETATION.BEC_BIOGEOCLIMATIC_POLY); OGMA (WHSE_LAND_USE_PLANNING.RMP_OGMA_LEGAL_ALL_SVW); Roads (WHSE_BASEMAPPING.DRA_DGTL_ROAD_ATLAS_MPAR_SP); Forest harvest (WHSE_FOREST_VEGETATION.VEG_CONSOLIDATED_CUT_BLOCKS_SP, WHSE_FOREST_TENURE.FTEN_CUT_BLOCK_POLY_SVW, WHSE_FOREST_VEGETATION.RSLT_OPENING_VW in directory RSLT_OP_VW); Protected areas (WHSE_TANTALIS.TA_PARK_ECORES_PA_SVW, WHSE_ADMIN_BOUNDARIES.CLAB_NATIONAL_PARKS).

^cExpressed as percentage of old-growth forests (ha) in this BEC subzone.

In the Kispiox ITR, logging has reduced old-growth forest cover to 31.7% (Table 1), a major decline for a region that would have historically been dominated by old-growth forests. Significantly, only 6.9% of old-growth forests in the Kispiox ITR occur in parks and protected areas, with another 8.7% in old-growth management areas (OGMAs) (Table 1)—a level of protection unlikely to ensure the long-term persistence of at-risk lichens like tarpaulin tarpaper (*Collema coniophilum*), smoker’s lung (*Lobaria retigera*) and cryptic paw (*Nephroma occultum*), all recently designated as threatened under Canada’s endangered species legislation (COSEWIC, 2019). Crucially, these figures are based on a 250-year threshold for recognition of old-growth forests, consistent with recruitment schedules of old-growth forest dependent lichens (Campbell and Fredeen, 2004; Goward and Arsenaault, 2018).

Compounding the relatively low level of habitat protection for old-growth forest in the Kispiox ITR is the highly irregular and elongate shape of many of the Kispiox ITR protected areas, especially OGMA reserves. With edge effects for old-growth forest-dependent lichens known to extend 100 m from the margins of clear-cuts (Gauslaa et al., 2018), many of the current protected areas in the Kispiox ITR will not provide the “interior” habitats required by such lichens once adjacent stands are logged.

The figures for the Caribou ITR are even lower, with old-growth forest cover (>250 years old) currently at 23% (Table 1). About a quarter of this old-growth is located in protected areas, notably Wells Gray Provincial Park, while a further 30% has received provisional protection as OGMAs; but see also Fig. 12. Ancient forest stands, where individual trees can reach 1000 years or more (Lewington and Parker, 1999), have been particularly vulnerable to logging in the Caribou ITR (Fig. 13). In the upper Fraser River watershed, for example, ancient western redcedar stands now occupy between 3% and 7% of the landscape, down from >30% historically (Radies et al., 2009) (Fig. 14).

Old-growth representation within the B.C. portion of the Interior Wetbelt is lower still, at only 4.6% (Table 1). Less than a quarter of these forests occur in parks and protected areas, with another 29% in OGMAs. The proportion of past cut blocks in this landscape is also the highest of any of the three regions examined, just below 30% in total (Table 1).

A major related concern is relatively high road density, mostly in the form of haul roads for logging operations (Fig. 12). Road density in excess of 0.6 km/km² is commonly used as a threshold in habitat degradation beyond which populations of large vertebrates begin to decline (Foreman et al., 1997). By comparison, road density currently stands at 0.84 km/km² in the Kispiox ITR (“Moist” ICH BEC subzone only), 0.99 km/km² in the Caribou ITR, and 1.37 km/km² in the Interior Wetbelt (B.C. only) (Table 1). Such densities are likely unsustainable for large-bodied species like moose (*Alces alces*) (Beazley et al., 2004) and grizzly bear (Nielson et al., 2009).

Compounding the effects of the loss of old-growth forests to logging in the ITR are the ongoing and predicted impacts of climate change. The climate envelope for the “Wet” and “Very Wet” ICH BEC subzones is predicted to shift dramatically by 2050, shrinking and moving upslope in the central and southern part of the Caribou ITR, while expanding outward to the central-interior plateau farther north, where more precipitation is forecast in the summer period (Stevenson et al., 2011). The potential loss of old-growth forests from valley-bottom habitats would have a major impact on the ITR, eliminating the very subset of stands with the greatest site continuity (time between major stand-level fires).

Recent research suggests that these impacts will be exacerbated by many of our current forest management practices. Lindenmayer et al. (2009) noted that logging of old-growth forests in humid regions like the ITR can significantly shorten fire-return intervals due to changes in canopy microclimate and fuel-loading. Bradley et al. (2016) similarly found that where forests in the western United States had higher levels of protected area designation, they had overall lower fire severity values, notwithstanding their

Fig. 12 The construction of forest access roads for logging has significant cumulative impacts on Inland Temperate Rainforest and Interior Wetbelt ecosystems, changing patterns of surface run-off and creating deleterious “edge effects” that can extend far into the adjacent canopy. The Fraser Flats Forest Access Road, shown here, was built through the middle of an Old Growth Management Area specifically set aside to conserve regionally rare ancient cedar stands in the Caribou ITR.

Fig. 13 The distribution of logging cut blocks (*light green*) within mountain valleys of the Caribou Inland Temperate Rainforest is heavily biased towards the lower slope position, often described as the “toe-slope” position, shown here in a Google Earth image (from 2007 Landsat image) for the McGregor River valley in the upper Fraser River headwaters (see location in **Fig. 14**). Historically, conditions in these lower slope topographic positions favored widespread development of ancient cedar stands.

Fig. 14 The proportion of sites currently occupied by ancient forest stands versus those that have been logged is shown by leading tree species (inset pie chart) for the Very Wet Cool Interior Cedar—Hemlock biogeoclimatic (BEC) subzone (ICHvk2) in the upper Fraser River watershed (Caribou ITR). Ancient forest stands were mapped by aerial photo interpretation (ILMB, 2004). Listed tree species are Cedar (western redcedar—*Thuja plicata*), Spruce (hybrid Engelmann-white spruce—*Picea engelmannii* x *glauca*), and Hemlock (western hemlock—*Tsuga heterophylla*). “Balance of Landscape” refers to areas in the ICHvk2 that would not have historically supported ancient forest stands due to topographic position, i.e., irrespective of their present-day status as “logged” or “ancient.” Data adapted from Radies et al. (2009). The reference area (forested ICHvk2 BEC zone) is 110,000 ha.

greater biomass and fuel loading levels. These findings highlight the need to protect existing old-growth forest ITR and interior Wetbelt stands to maintain ecological resiliency in the face of climate change.

Conclusions

The cumulative environmental impacts of resource extraction and climate change on the Inland Temperate Rainforest and Interior Wetbelt can only be managed effectively when they are anticipated and addressed proactively through effective conservation policy and land-use regulations. With the ongoing loss of old-growth forest ecosystems comes the inevitable loss of resiliency for many species that depend on them (Baldwin and Bradfield, 2010). Given the collapse and pending extirpation of most deep-snow mountain caribou herds, it is clear that critical disturbance thresholds, beyond which the decline and extirpation of old-growth forest dependent taxa begins, have been reached across the ITR and Interior Wetbelt.

We recommend an immediate moratorium on clear-cut logging in forest stands older than 250 years in age within the Kispiox and Caribou ITR. Given the extreme rarity of old-growth forests stands in the Interior Wetbelt, remaining old-growth forest stands exceeding about 150 years in age should be designated as protected areas. Management plans in all three regions should include measures to ensure that remnant old-growth forest stands are buffered from the adverse impacts of adjacent cut-blocks (see discussion in Chapter 11, Stevenson et al., 2011) and are incorporated into a network of conservation areas, providing connectivity and safeguarding critical habitat.

Finally, comprehensive steps towards broader landscape-level restoration of old-growth forest ecosystems should be put in place immediately within the Kispiox, Caribou, and Interior Wetbelt ecosystems. This will require measures that allow existing younger to mature forest stands to remain undisturbed for long periods of time, particularly where they provide conservation corridors between remnant old-growth forest stands. This will be especially important in topographic sites such as wet “toe-slope” positions, locations which historically would have been occupied by old-growth forest stands. Restoration ecology efforts should be guided by our knowledge of the natural range of variability in temperate rainforest ecosystems (Agee, 2003; DeLong, 1998; Pearson, 2010; Wong et al., 2003).

Crucial to achieving these goals are key changes in forest management practices across the timber-harvesting land base. Included here are longer logging rotations, adoption of partial-cutting silvicultural systems, and efforts to reduce cut block dispersal (DeLong, 1998; Stevenson et al., 2011). An important example of how such conservation planning can be integrated across a mosaic of protected areas, conservation corridors, and designated harvest-intensity zones is the Great Bear Rainforest (GBR) Conservation Accord which recently came into effect in coastal B.C. (MFLNRO, 2016; Price et al., 2017). Significantly, this initiative was achieved, in part, through greater recognition of Aboriginal rights and title (Curran, 2017), a significant issue in many parts of the Inland Temperate Rainforest and Interior Wetbelt regions (see CBC, 2019).

Abstract

Boreal forests, or taiga, are the Earth's northernmost forests, covering vast tracts of land across Alaska, Canada, northern Europe, Russia and northeastern China, between the arctic tundra to the north and cold-temperate forests and grasslands to the south. The most characteristic climatic features are long duration of snow cover and short cool summers. They are among the world's leading purveyors of ecosystem services, including carbon storage and clean water, and they have a large impact on climate at local, regional and global scales. Boreal forests harbor globally significant wildlife populations, including songbirds, migratory waterfowl, bears, wolves, moose, lynx and Siberian tigers. Spruce, fir, pine and larch dominate these forests along with birch and aspen. Boreal forests are flammable, and large fires which renew forest ecosystems and regulate their value as wildlife habitat are common. Trees and other plants in the boreal biome have many adaptations to fire, such as abilities to store seeds in serotinous cones or in the soil for release after a fire, sprouting from the stump or roots, or thick bark that insulates trees from fire. Although large tracts of unlogged, primeval forest are still present, unsupervised logging, mining, oil extraction and climate change pose threats.

Introduction

Boreal forests (also known as taiga) are one of the world's leading purveyors of ecosystem services including carbon storage and clean water (Schindler and Lee, 2010). Boreal forests have a large impact on climate at local, regional and global scales (Snyder et al., 2004). They also harbor globally significant wildlife populations (Schmiegelow et al., 1997), and large tracts of unlogged primeval forest are still present which show how natural disturbances, landforms, and ecosystem processes work to maintain biodiversity (Bengtsson et al., 2000; Wardle et al., 2012; Frelich, 2017).

With 12.1 million km², boreal forests comprise 33% of all forests on the Earth (Kuusela, 1992). They cover vast areas in the northern hemisphere, across North America (central Alaska to Labrador, Canada), northern Europe and Asia (Norway, Sweden, Finland, and Russia), with a few excursions of small extent into the northern conterminous United States, China and Mongolia (Fig. 1). The term "circumboreal" has been coined to describe the belt of boreal forests that circles the globe (i.e., it occurs at all longitudes with suitable land) at high latitudes. Russia and Canada have the largest proportions of boreal forests (65% and 27%, respectively), while Scandinavia and the U.S. have much smaller portions with about 4% each.

Physiognomy, Climate and Relationship With Adjacent Biomes

Boreal forests are closed-canopy conifer forests with a significant admixture of deciduous trees (Fig. 2A and B). They are also the world's coldest forests; dominated by the most cold-tolerant tree species, conifers—spruce (*Picea* spp.), fir (*Abies* spp.), pines (*Pinus* spp.) and larch (*Larix* spp.), with variable admixtures of cold-tolerant deciduous tree species; birch (*Betula* sp.), alder (*Alnus* spp.) and aspen (*Populus* spp.). Boreal species within these genera can withstand extreme winter temperatures as low as -80°C (Brandt, 2009) by moving water outside of cell walls, or outside of sensitive organs such as buds. These mechanisms of cold tolerance are superior to the deep supercooling mechanism that occurs in trees of the temperate zone, which are limited to -40°C to -45°C (George et al., 1974). Regardless of winter survival, boreal tree species are also capable of growing in areas with very short summers compared to trees of the temperate biome.

Boreal climates are characterized by long, cold, snowy winters, and short, cool summers (Peel et al., 2007). With some exceptions discussed below, they lie in the region between the summer position of the arctic front on the north and the winter position of the

Fig. 1 Polar-view map of the boreal biome. Courtesy of David Wilson, University of Minnesota.

arctic front on the south. Within this region, summers are long and warm enough for boreal tree species to complete their life cycle—3 months with mean temperatures in the range of 10–17°C. Towards the south, in regions with continental climates, winters may be cold enough to exclude temperate tree species by directly killing them in cases where their limit for winter minimum temperature is regularly exceeded. These regions have “winter boreal” climates, and in mid-continental southern boreal areas with relatively warm summers, boreal forests are maintained against invasion by temperate forests by winter cold. However, some southern boreal forests in areas of maritime climates have relatively mild winters compared to interior continental boreal forests, although summers may still be too short and/or too cool for temperate tree species to complete their life cycle or to effectively compete with boreal tree species—so called “summer boreal” climates. These occur near large, cold water bodies, and occur in areas close to the ocean, such as Newfoundland, Canada, parts of Scandinavia, and the Great Lakes of North America.

The circumboreal belt at northern latitudes occupied by boreal forests extends from the edge of arctic tundra on the north, to cold-temperate climates on the south, where they mingle either with grasslands in dry interiors of North America and Eurasia or temperate forests dominated by oak (*Quercus* spp.), maple (*Acer* spp.) and basswood or linden (*Tilia* spp.) in eastern Canada and the United States and northern Europe, eastern China, Korea, and Japan. Boreal forests also intergrade with high elevation montane forests, many of which have very similar physiognomy and species composition at the generic level, with spruce, fir, birch and aspen. These montane forests extend south of the boreal zone in high-elevation places such as the Rocky Mountains in North America and Ural Mountains in Russia. Boreal forests are usually divided into northern, with low productivity and often low density

of trees on permafrost, and southern boreal with relatively productive forests on suitable sites (although still lower in productivity than temperate or tropical forests).

The region with mixed forests of boreal and temperate species to the south of purely boreal forests is referred to as hemi-boreal or near-boreal forest (Fig. 3, Jögiste et al., 2017). In eastern North America, northern Europe and eastern China, these hemi-boreal forests gradually change along a climate gradient from nearly pure boreal with small inclusions of temperate forest, to nearly equal mixtures, to nearly pure temperate forest with small inclusions of boreal vegetation (Fisichelli et al., 2014). Mean summer temperatures generally range from 17–19°C in this transition zone, and there are generally 4 months with mean temperatures above 10°C. At the northern edge of hemi-boreal forest, temperate forest inclusions occur on south-facing slopes. At the southern edge of hemi-boreal forest, small areas of boreal vegetation occur in basins with cold air pooling at night, north-facing slopes with cold water seepage, and upwelling of cold water on the shores of large lakes that cause summer climates cool enough for boreal species. These isolated boreal forests are often advanced colonies responding to the generally cooling climate of the late Holocene (ca. last 4000 years), although some have persisted through the mid-Holocene warm period, prior to which their surrounding landscape was all boreal, and are true relicts. Both types of boreal inclusions occur as much as 200–300 km south of the main range of the boreal forest.

In addition, stands of boreal species occur naturally on sites with rocky or sandy, nutrient-poor soils within the temperate biome, such as Jack pine (*Pinus banksiana*) in North America, or were planted on such sites, e.g., Scots pine (*P. sylvestris*) in Europe. However,

Fig. 3 Hemiboreal forest in Estonia, regenerating after a windstorm, with trembling aspen (*Populus tremula*), mountain ash (*Sorbus aucuparia*), Norway spruce and Norway maple (*Acer platanoides*). Photo by Kalev Jõgiste.

these forests are commonly mixed with temperate tree species that are clearly capable of growing on rocky and sandy soils. Therefore, climate is the main factor leading to the development of temperate or boreal forests, rather than poor site conditions. Also in the temperate zone, human activity has led to artificial “borealization” of landscapes in parts of Europe, where the boreal species Norway spruce (*Picea abies*) has been widely planted.

In some interior continental regions (central North America and Eurasia), southern boreal forests form an ecotone with grasslands. Drought stress is a limiting factor for trees in these regions. A positive balance between annual potential evapotranspiration and precipitation is needed for development of forests, and determines the location of the boreal forest-grassland ecotone (Hogg, 1994). Mosaics of boreal woodlands and grasslands (referred to as aspen parkland in North America) can occur due to differential water-holding capacity of soil bodies, and north/south slopes with different moisture balances in this forest-grassland ecotone. In addition, high fire frequencies in grasslands can prevent tree growth for variable distances into the zones with climates potentially favorable for boreal forest.

Soils and Ecosystem Development

Much of the boreal forest lies on young glaciated, rocky landscapes with numerous lakes, or on glacial drift—for example the Canadian Shield of exposed rocks that underlies the boreal forest of central North America (Fig. 4). Cold temperatures with low decomposition and evaporation rates lead to sphagnum peatlands on wet sites and thick organic horizons (duff layer or forest floor) on well-drained sites. Some of the boreal forest also lies on older soils that escaped glaciation in northern Alaska and Siberia. Upland soils are generally classified as spodosols (United States) or podzols (Europe and Asia). These distinctive soils have thick organic horizons with distinct litter, fragmentation (or fermentation) and humus layers, underlain by an eluvial horizon which is light in color and an illuvial horizon where iron leached from the upper A horizon is deposited. There has been extensive formation of peatlands in the boreal biome over the last few thousand years, with deep organic (histosol) soils.

Surprisingly, ecosystem retrogression—ecosystem aging, a progression from the maximal biomass phase to the retrogressed phase with lower productivity and biomass (Peltzer et al., 2010)—occurs relatively fast in boreal ecosystems compared to temperate and tropical forests. This can be caused by chemical processes that occur in cold environments. Ecosystem acidification, a process by which production of organic acids, by sphagnum mosses, coniferous needles, and slow decomposition of organic matter on the forest floor, can eventually overwhelm chemical buffer systems in soils and lakes (Ford, 1990). In uplands, accumulation of organic forest floor material and mosses retain water and insulate the soil, leading to shorter growing seasons for roots, or even permafrost in northern boreal regions, in turn leading to waterlogging, low availability of nutrients (especially nitrogen) and stunted tree growth—a process very common in boreal forests and known as paludification. If most of a watershed has paludified soils, then lakes can also be acidified, leading to loss of fish species diversity, and some lakes can convert to bogs with floating mats, very low pH and no fish.

Fires can be a renewal process that retards acidification and paludification by removing the organic horizon and liberating cations (Ca, K, Mg) which neutralize acids—therefore fires are an integral renewal process important to maintain forest productivity over long periods of time (millennia, Payette et al., 2012). Retrogression from a maximal state of biomass production allowed by

Fig. 4 Black spruce (*Picea mariana*) forest on Canadian Shield exposed bedrock in central North America. Photo by Elias Anoszko.

the soils and climate of a given boreal forest, to a retrogressed state with stunted vegetation can occur within several centuries to a few millennia in the absence of fires. This could occur in small areas—refugia sheltered from fire by landform on landscapes with frequent fire—or over entire landscapes in boreal regions where fires are rare. An example of the former is southern boreal forests with high-severity crown fires every 50–100 years in central North America (Saskatchewan, Manitoba, and western Ontario, Canada) while the latter occurs more frequently in places with wet climates like eastern Quebec, Canada, or northern Sweden.

Aquatic and Wetland Features

The boreal biome comprises enormous fresh water resources. The two countries that comprise the vast majority of boreal forest, Canada and Russia, have the first and second largest areas of fresh water in the world, respectively. Millions of lakes, large river systems, and extensive wetland complexes with sedge meadows, marshes, bogs and forested swamps are common within the boreal biome. Glacial lakes carved in bedrock, or in kettle holes of glacial outwash plains are numerous in boreal forest regions such as central North America and Finland. Superior, Great Bear, Great Slave, and Athabasca in North America, and Baikal in Russia are among the world's largest lakes with >30% (by volume) of the world's surface fresh water. Vast river systems occur on relatively flat lands between mountain ranges, or on plains that have arisen from the ocean after the departure of glaciers via isostatic rebound (the latter includes the clay belt along Hudson's Bay in northern Ontario and land adjacent to the northern Baltic Sea in Sweden). Most of Russia and Canada are in the Arctic Ocean drainage basin with huge rivers such as the Ob, Yenisey, Lena and Amur Rivers in Russia, and the Mackenzie, Nelson and Yukon Rivers in North America. All of these are among the world's largest rivers and drain water from vast swathes of boreal forest and tundra.

Although acidic peatlands occupy vast acreages, high pH wetlands and lakes also occur where nutrient input from weathering of rocks such as basalt or limestone occurs. Surprisingly, the pH of many lakes can be in the range of 6–6.5, and the lakes are buffered by cations that are replenished by intense fires in the watershed, even on landscapes with nutrient-poor granitic bedrock (Leys et al., 2016). These lakes are able to support diverse food webs with many species of fish.

Peat bogs and lakes with sediments that date to the last glaciation, or much older, occur throughout the boreal forest, so that paleoecological reconstructions of ecosystem development since the last glaciation are possible, based on fossil pollen and macrofossils such as buds, seeds and needles or wood. Thus, it is possible to paint a picture of change with climate during the Holocene Epoch (the last 11,700 years); especially the mid-Holocene warm spell (centered around 5000–7000 years before present) can be used as an analog for a future moderate climate warming scenario, since summers were generally about 2°C warmer.

Flora and Fauna

With a few exceptions plant species are hard to pin down as strictly boreal. Among tree species, for example, black ash (*Fraxinus nigra*) and northern white cedar (*Thuja occidentalis*) in North America and Scots pine (*Pinus sylvestris*) and Norway spruce (*Picea abies*) in Europe occur at high abundances in both temperate and boreal forests—their ranges are split basically 50:50 between the two biomes—although further east in Russia Scots pine is almost totally located in the boreal biome. Gray alder (*Alnus incana*, with

various varieties in North America, Europe and Asia), Quaking aspen (*Populus tremula*) in Eurasia and *P. tremuloides* in North America, Jezo spruce (*Picea jezoensis*), Silver birch (*Betula pendula*), Paper birch (*Betula papyrifera*), and Siberian silver birch (*Betula platyphylla*), are among the species that are important across huge expanses of boreal forests, but which also occur extensively in temperate forests.

White spruce (*Picea glauca*), black spruce (*P. mariana*), tamarack (*Larix laricina*) and balsam poplar (*Populus balsamifera*) occur at the edge of arctic tree line and throughout the boreal forest, while balsam fir (*Abies balsamea*) occurs mostly in the boreal biome of North America. In Eurasia, Dahurian larch (*Larix gmelinii*), Siberian larch (*Larix sibirica*), Siberian spruce (*Picea obovata*), Siberian pine (*Pinus sibirica*), and Siberian fir (*Abies sibirica*) occur mostly in the boreal biome. These species are more properly classified as boreal, although they also occur to some extent in colder parts of the temperate biome.

One of the unique features of biodiversity in boreal forests is the large number of circumboreal plant and wildlife species—namely the same species occur at all forested longitudes at the latitude of boreal forest. There are also cases where species are different, but the genera are in common between the two land masses in North America and Eurasia. For example there are few, if any, circumboreal tree species—the genera are circumboreal, with similar species in Eurasia and North America. This similarity at the species and generic taxonomic levels has come about because Alaska has been periodically joined to Russia during glacial periods, allowing migration of species and genetic exchange from Eurasia to North America.

Circumboreal herbaceous plants include twinflower (*Linnaea borealis*), bearberry (*Arctostaphylos uva-ursi*), and Lingonberry (*Vaccinium vitis-idaea*). Forest floors in boreal forests have complex microhabitats, with decaying coarse woody debris, snags, tip-up mounds, rocks, and arboreal surfaces, with large variability in light availability, allowing for a diverse assemblage of mosses, clubmosses, ferns and small herbaceous plants that make up the plant community (Fig. 5A and B).

Very large species richness of mosses and lichens occurs in boreal forests (Fig. 5C and D), because the climate favors species with those growth forms, and because of the microhabitat variability. The three feather moss species red stemmed feathermoss (*Pleurozium schreberi*), splendid feather moss (*Hylocomium splendens*) and ostrich plume feathermoss (*Ptilium crista-castrensis*), as

well as a number of *Sphagnum* species, are very abundant on the forest floors of moist boreal forests across vast extents. Well-drained sites feature species of reindeer moss (lichens in the genus *Cladonia*) and a set of moss species adapted to dry microhabitats.

Boreal forests are habitats for iconic, large wildlife species. Circumboreal species with ranges mostly in the boreal forest include moose (*Alces alces*, also called Elk in Europe), Woodland caribou (*Rangifer tarandus*, also called reindeer in Eurasia), Gray wolf (*Canis lupus*), Wolverine (*Gulo gulo*), Brown bears (*Ursus arctos*, also called grizzly bears in North America). Additional wildlife species include the Lynx—a circumpolar genus with two species (Eurasian lynx, *Lynx lynx* and Canadian lynx, *Lynx canadensis*), the endangered Siberian tiger (*Panthera tigris tigris*) with a small range in far eastern Russia and northeastern China, and the wood bison (*Bison bison athabasca*) in western Canada, and Black bear (*Ursus americanus*) in North America.

Long-term studies, over several decades, of trophic relationships among boreal wildlife species are quite famous. One example is the 8–11 year cyclic relationship between Lynx and Snowshoe hare in Canada, due to interactions of predation and food supplies. The hares overgraze plants in their habitat, undergo a population crash, stabilize for several years and then increase when the plants recover; lynx populations rise and fall with the hares, but with a few years delay due to their longer life cycle (Krebs et al., 2001). Another case is the 50+ year study of moose and wolves on Isle Royale National Park, a large island in Lake Superior, United States. Here, the moose population is sometimes regulated by wolves, and sometimes not, due to fluctuations in wolf population caused by a variety of fluctuating factors, including winter snowfall and population revitalization by new individuals migrating from the mainland over an ice bridge that forms at irregular intervals in recent years, due to the warming climate (Adams et al., 2011).

The boreal forest provides habitats for massive numbers of migratory and non-migratory birds. The neotropical migrant birds in North America include many species of warblers and thrushes that spend the winter in the Caribbean, Mexico or South America. Massive flocks of waterfowl—geese, ducks and pelicans—inhabit boreal forests during the summer. Resident circumboreal bird species include the raptors Golden eagle (*Aquila chrysaetos*) and Great gray owl (*Strix nebulosa*). Separate but related species of boreal grouse occur in North America and Eurasia, Spruce grouse, and Siberian spruce grouse (*Falcapennis canadensis*, and *Falcapennis falcapennis*, respectively), while the Blackbilled capercaillie, (*Tetrao urogalloides*) is a large grouse that occurs only in Eurasian forests.

Fire and Adaptation to Fire

Many vast tracts of boreal forest are still intact ecosystems, allowing opportunities to characterize ecological processes little influenced by human activities. This includes disturbance regimes and their relationships to landscape patterns. Coniferous boreal forests are among the world's most flammable fuel types and regularly support some of the largest fires on Earth. These fires regulate the nature of the landscape mosaic of vegetation and the process of succession—replacement of early successional species that appear right after fire by late-successional species. The vegetation mosaic in turn determines which wildlife species can live on the landscape, since wildlife species depend on proportions and spatial distributions of successional stages.

One of the fascinating aspects of boreal ecology is how plants are adapted to the high occurrence of fire. Two tree species that are mainstays of the North American boreal forest—jack pine and black spruce—have serotinous cones. Their cones remain closed in the canopy until the heat of a fire opens the scales, allowing seeds to be shed. This is an adaptation to infrequent, high-severity fire (return times of 50–150 years), that assures that a post-fire cohort of newly germinated seedlings will replace mature trees killed by a fire (Fig. 6A and B). Several years of cone/seed production is available to be distributed whenever a fire occurs, and whether or not a fire occurs during a mast year with high seed production is not important. These species typically grow in dense stands with high canopy bulk density, which facilitates spread of high-intensity fire. In a sense, the adult trees sacrifice themselves by promoting fire, although such fires also kill competing late-successional species such as balsam fir, that would otherwise replace jack pine. These

Fig. 6 Regeneration by serotinous seed after high-severity fire. (A) Post-fire jack pine (*Pinus banksiana*) forest. Photo by Dave Hansen. (B) Regeneration 6 years post fire. Photo by Elias Ansozko.

Fig. 7 Regeneration by sprouts and buried seeds after high-severity fire. (A) Stump sprout of a top-killed paper birch. (B) Jack pine and black spruce forest 1-year post fire—seedlings are pin cherry germinated from buried seeds. Photos by Dave Hansen.

forest types may have little succession for centuries; regeneration mirrors the pre-fire canopy composition and only a small proportion of stands across the landscape are missed by fire and become old enough to undergo succession (Johnson, 1992).

Post-fire sprouting is another important strategy. The circumboreal birch and aspen species, as well as shrubs such as hazel (*Corylus cornuta*), mountain maple (*Acer spicatum*) and willows (*Salix* spp.) sprout after fire (Fig. 7A). Depth of burn into the forest floor tends to be low in spring fires, and deeper in summer or fall fires. Therefore, spring fires favor regeneration of aspen (with root sprouts throughout the spatial extent of the root system and spring seed dispersal), while summer/fall fires favor birch (with stump sprouts and fall seed dispersal).

Seeds of both the birch and aspen genera are small, with good long-distance dispersal, so that these species can also return post fire via a long-distance seed dispersal strategy if sprouting should fail. The circumboreal species with bright magenta flowers, known as fireweed (*Chamaenerion angustifolium*), also has plumed seeds and a long-distance seed dispersal strategy to colonize post-fire environments.

A final seed-related adaptation to fire, is the buried seed strategy. Pin cherry (*Prunus pensylvanica*), a small boreal tree species, and Bicknell's geranium (*Geranium bicknellii*) are two species that require sunny post-fire environments that help to quickly revegetate soils right after fires, preventing erosion. These species produce large seed crops during early succession after fire, which fall on burned soil and become buried in the forest floor. These seeds survive for decades or even centuries, and germinate when they detect light after a subsequent fire (Fig. 7B).

Pine and larch species (e.g., red pine in North America and Scots pine in Eurasia) can resist the effects of fire, and grow in climates or on landforms that promote more frequent fires than species that employ a serotinous seed strategy. These trees species are tall with thick bark, have good self-pruning of lower branches, and bear their foliage high above the forest floor when mature. These traits help to avoid scorch of the cambium underneath the bark or the foliage during surface fires. Individual trees can be scarred at the base by fires, but can survive for centuries afterwards. Most years for seed production are common in these species, and it may take several mast years to gradually reseed the forest over a few decades, in addition to having several cohorts of trees that germinated after fires, resulting in mixed age stands (Fig. 8).

Finally, some species employ a fire avoidance strategy. White spruce and balsam fir are explosively flammable, with pitch in their sap, high foliar density, and thin bark that allows girdling of the cambium at the base of the tree very easily during fires. Why would such species exist and grow on a landscape where fire is a major force? There are many places—fire refugia—on the landscape, especially in recently glaciated terrain, where fires do not occur. During periods of time when fires are not as frequent (return time for fires varies over the centuries with fluctuations in climate), these species advance from their refugial locations and cover significant proportions of the landscape, however, during times of frequent fire, they persist, restricted to the refugia. Many landscapes, such as the Canadian shield, have numerous fire refugia caused by rock outcrops, forested swamps, open wetlands and lakeshores. These species also dominate in regions with wet climates.

Successional Dynamics in the Boreal Forest

When the fire regime and adaptations of the dominant tree species are in synch with each other, fires can maintain the same composition of tree species for centuries; alternatively, fires can lead to replacement by different sets of tree species and initiate a succession sequence (Frelich, 2002) as follows.

- Frequent low-severity regimes. These can occur in southern-boreal larch and pine forests—species with the resistance strategy—on dry interior continental sites near grassland-boreal ecotones. Stands have open understories with fires every ca. 5–40 years.

Fig. 8 Uneven-aged Scots pine forest with young and old post-fire regeneration cohorts, and fire-scars at the base of the larger pines. Photo by Kajar Köster.

Regular ignitions are caused by lightning or indigenous peoples maintain such forests. Purposeful burning to maintain wildlife habitat or to regenerate food plants (e.g., blueberries in North America) was, and still is in some regions, a common practice.

- Mixed-severity fire regimes can have frequent low-severity fires, with occasional high-severity fires, and are also dominated by tree species with the resistance strategy. Such regimes have a lot of spatial and temporal variability in fire size and severity; sprouting and serotinous species are often mixed with the fire-resistant species (Figs. 7A and 8).
- Infrequent high-severity fire regimes occur on landscapes dominated by species with the serotinous cone or sprouting strategies. On conifer-dominated sites, little succession occurs as long as fire intervals are longer than the time needed for the conifers to build up canopy-stored seeds (10–20 years) but not longer than it takes for fire-sensitive, shade tolerant species to invade (>150 or 200 years). This is especially common on rocky terrain with low-quality soils, such as the Canadian Shield. On better quality sites in the southern boreal, alternation of deciduous (birch and aspen species) and fire-intolerant coniferous species (persisting in nearby refugial locations) can occur. This represents genuine succession from birch and aspen to shade tolerant conifers, which is reset to deciduous species every time a severe fire occurs. Note that succession to conifers is needed to facilitate severe fires.
- Infrequent fire regimes exist on islands, in forested wetlands, and in regions with constantly wet climates. Disturbance regimes are dominated by gap dynamics due to treefall and insects. Derechos (severe thunderstorms with straightline winds) occur in continental interiors, and heavy wet snow events in autumn and spring also take down trees. Insects such as spruce budworm (*Choristoneura fumiferana*) in eastern North America, which infest balsam fir in the southern boreal forest, and bark beetles on spruce and larch species, are common causes of individual tree death in areas without severe fires. Late-successional dominance can be perpetuated for many generations of trees, until interrupted by fire.

Threats

Boreal forests are susceptible to climate change and vast areas are now being logged, flooded for hydro power, stripped to access tar sands, or subjected to mining deposits of metals such as iron, nickel and copper (Saucier et al., 2015).

Boreal forests play an important role in the Earth's atmospheric cycles, including its huge carbon pool. Not only the trees that cover vast acreages sequester carbon; boreal soils have slow decomposition rates, and large buildups of forest floor organic material, and moss blankets in many places. Boreal forests have been sinks for carbon, or close to equilibrium with fires and decay processes at the continental and global scales. However, boreal forests are expected to become net sources of CO₂ to the atmosphere, as fire frequencies increase in a warming climate (Flannigan et al., 2009). More fires combined with logging lowers the average age of stands across the landscape. Finally, invasive earthworms from the south or other continents are consuming the forest floor (Cameron et al., 2015). These factors can decrease carbon storage on boreal landscapes.

Boreal forests have long histories of migration over large ranges of latitude with numerous glacial cycles during the Quaternary Period of the last 2.6 million years. The forests that we are familiar with today disappear during glacial maximums, when the boreal forest is slowly pushed south into temperate latitudes. In Europe and central North America, the broad range of the boreal forest is pushed into a relatively small area and mixed with temperate tree species during peak glacial cycles, and the vast, far northern extent of boreal forest we are familiar with today develops anew during each interglacial.

The problem with human-driven climate change during the 21st century is that we are starting from a warm interglacial climate and will proceed into super-interglacial conditions that probably have not existed since the Neogene Period (23 million–2.6 million ybp). Boreal forests may run out of room; as temperate tree species or grasslands infiltrate the southern boreal, the northern edge of the boreal is pushing northwards as well, onto lands currently occupied by arctic tundra. At some longitudes—e.g., northern Scandinavia and north central Canada—there is not much room for northwards movement of the boreal forest before it runs into the Arctic Ocean, or Hudson Bay, respectively. At the same time, the Arctic Ocean will move southwards due to sea level rise associated with warmer climate, leaving the boreal forest with much less room. In any case, the boreal forest is headed for a unique future that will require novel management solutions.

There are several mechanisms by which a warming climate can kill the southern boreal forest:

- Gradual infiltration of temperate tree species through gap dynamics as boreal tree species die. This can occur whenever the temperature regime becomes suitable for temperate species (i.e., release from very cold winter minimum temperatures or short/cool summers) and the seed sources are available (Fisichelli et al., 2012, 2014, Fig. 9A).
- Rapid conversion from boreal to temperate tree species when wind storms remove large swaths of boreal forest and suddenly release temperate understory trees. There are many forests in the southern boreal region with boreal (e.g., *picea*, *Abies*, *Betula*) overstories and temperate (*Acer*, *Quercus*) understories (Fig. 9B).
- Compound disturbance such as wind storms followed by high-intensity fires, leading to conversion from conifer-dominated boreal forests to deciduous-dominated forests of birch and aspen (Fig. 9C), or temperate forest dominated by disturbance adapted temperate species, for example red maple (*Acer rubrum*) or bur oak (*Quercus macrocarpa*).
- Heat and drought stress killing large swaths of boreal forest along the prairie-forest border with replacement by grasslands or savannas. This scenario could occur if rising temperatures cause a negative precipitation-evaporation balance. Massive mortality of aspen (*Populus tremuloides*) forests has already occurred via this mechanism along the southern edge of the boreal forest in Alberta and Saskatchewan, Canada (Michaelian et al., 2011).
- Insect infestation (native and exotic insect species) due to lack of extreme cold that formerly kept insect populations at bay, could kill large areas of boreal forest (Logan et al., 2003). For example, mountain pine beetle (*Dendroctonus ponderosae*), although

Fig. 9 Climate-related changes in forest regeneration. native in western North America, has exploded in recent years after a run of several warm winters, and has killed millions of hectares of lodgepole pine (*Pinus contorta*). This insect pest may be able to reach boreal forests in eastern North America dominated by jack pine, which has been shown to be a suitable host (Rosenberger et al., 2017).

Although most models project gradual change from boreal forest to temperate forest or savanna, most of these mechanisms have the capability to quickly transform large swaths (tens to millions of km²) of boreal forest to other vegetation types. Therefore, many large surprises are likely to occur in the southern boreal forest over the next century, with major impacts on forest productivity, ecosystem services, and wildlife habitat.

Conservation Initiatives

If the future super-interglacial world materializes, a number of important questions arise: Where will boreal forest be replaced by other biomes? On such landscapes where will the remnants or climate refugia occur? Where will new boreal forest appear in former tundra? Scientists are working on answers to these questions.

Climate refugia are defined as “areas relatively buffered from contemporary climate change over time that enable persistence of valued physical, ecological, and socio-cultural resources” (Morelli et al., 2016). For refugia, the past is the key to the future; refugia of boreal forests in a warmer world can be studied by examining past refugia that formed as the glaciers retreated 18,000–6000 ybp. For example, early Holocene (ca. 11,700 ybp) boreal forests in the Midwestern USA—Minnesota, Wisconsin and Michigan—were replaced by temperate forests of oak, maple, elm and basswood between 11,000 and 6000 ybp. However, small-to-medium sized landscape features, 10s–1000s of hectares in size, retained boreal forests for millennia, some even until today. These included numerous lowlands that regularly experience cold air pooling at night, which became peatlands where black spruce or tamarack forests persisted to the present day. Some boreal forests also persisted in areas near large lakes with cold-water upwelling. Perhaps the most famous example is on the Door Peninsula of Wisconsin in Lake Michigan, where boreal forests persist due to cool summer temperatures brought in by lake effect breezes that pass over cold upwelling water just before coming ashore, creating a narrow belt (1–3 km wide) of boreal forest along the shore. Studies are underway to find future climate refugia like these within the current extent of the boreal forest. Boreal forest may persist locally in these refugia, even as the surrounding landscape becomes temperate forest or even grassland.

Major initiatives in boreal forest conservation include the Boreal Songbird Initiative of the Pew Charitable Trust, The World Wildlife Fund (WWF) Forests Program, the Boreal Conservation Framework, and The Nature Conservancy Boreal Conservation Program. These programs seek to reserve large areas of land from development and timber harvesting, and to develop best management practices (BMPs) to make harvesting more compatible with natural disturbance regimes (e.g., close to nature forestry) in other areas. Due to the remoteness of the boreal forest, setting aside very large acreages from development is feasible, and has happened in parts of Canada, United States, and Russia.

BMPs are partly government regulated and partly accomplished through certification of forest management and chain of custody (following certified wood from harvest through products to the consumer). The Forest Stewardship Council (FSC) and Programme for the Endorsement of Forest Certification (PEFC) are non-government, non-profit certification organizations with guidelines for proportion of acreage harvested annually within a given ownership, as well as considerations for maintaining biodiversity, wildlife, water quality, and indigenous rights. About 10% of forest land worldwide, and in the boreal forest, is registered in one or both of these certification programs. Proportions of certified land are much higher in the temperate forest biome, suggesting room for improvement in boreal forests. However, large acreages of boreal forest are registered with one or both certifying agencies in Canada, Sweden, Finland and Russia (FSC, 2018; PEFC, 2018).

Conclusions

Boreal forests comprise one third of all forests on the planet; due to their remoteness and cold climate, many large intact boreal ecosystems still exist. Due to their importance to ecosystem services, wildlife and water resources, at regional and global scales, many efforts are underway to preserve and improve management of boreal forests. However, because of warming climate, large changes are likely to occur in the southern half of the boreal forest over the next several decades, including death of boreal trees caused by several mechanisms, and replacement by temperate forests or grasslands. This transition will be messy, but could be minimized by mitigating CO₂ emissions, by, for example, strictly following the COP21 Paris Climate Accords. Using history as a key to the future, scientists are working to develop solutions for managing change in the boreal forest.

Abstract

One of the world's densest geo-climatic, evolutionary, and ecogeographic diversities alongside low density human populations gives the Klamath bioregion a huge advantage in maintaining most of its biodiversity into the next century. With sufficient protection from and mitigation of major anthropogenic drivers of genetic loss at most scales, Klamath species will continue to accumulate species largely as a result of a high habitat density. This spurs speciation and migration and slows extinction rates due to nearby refuges quickly accessed even during rapid climate change. Unless temperatures reach mid-Pliocene levels in a geologic instant, speciations, and migrations will remain high and are likely to increase. However, one labels the enchanting intricacy of this bioregion, conserving its biodiversity in all its major forms and processes highlights the need to know and to care for that which is rare.

Introduction

The near perfect geographic match of the Klamath Mountains province with its bioregion underlines one of the world's great synergies of rock, water, and life.

Dozens of mountain uplifts and gravity or erosional deflations dominate Klamath geo-history. Some of these events and processes are so geologically recent or uneven in intensity that jagged peaks seem somewhat evenly interspersed with older flatter surfaces and newer river terraces, a topographic pattern that tends to maximize biodiversity. Meeting moist winter air from the Pacific Ocean with this topography creates one of the world's densest and most diverse set of rain shadows, soils, slope types, and drainage networks. How much water the Klamath's five ranges catch and hold drops dramatically in moving downhill or from west to east, with over 3.5 m annually near the coast and down to less than half a meter in deep valleys just tens of kilometers inland.

More specifically, the collusion of geology and biology together defines biodiversity centers and biologically porous borders much more than just geography. The diffuse, gradual bio-boundaries of the Klamaths speak of the many habitats that the bioregion shares with adjacent bioregions. This overlap has aided migrations, especially those from adjacent biodiverse mountain ranges, four of which together uniquely link up with the Klamaths.

Like most anything that builds Klamath biodiversity, what makes the bioregion so special is neither straightforward nor singular. It's more likely to be the sum of all the relicts, endemics, hybrids, migrants, range limited taxa, their main subdivisions, and processes known and unknown that may be as high per hectare in the Klamaths as most anywhere else.

Far <1% of visible Klamath taxa has been studied beyond scientific descriptions that briefly describes how their locality, anatomy, and/or genetics compares to near relatives. That suggests that the number of taxa that highlight many of the bioregion's diversity processes are at least an order of magnitude more than what hundreds of studies have shown. Yet perhaps the most telling argument for the Klamath's exceptionalism is that most other regions with similar geo- and biodiversity would cover much more area than the 25,595 km² or so of the Klamaths.

Climatic complexity in such a limited space but mind numbing timespans fostered a greater sum, density, range, and/or accumulation of soils, topographies of erosion and uplift than most other bioregions. All this promotes a higher density of taxa than that which occurs in most other extra-tropical regions and in many places closer to the equator. Some 70,000 nonmicrobial species embody a broad range and density of taxonomic scales and trophic levels of generalists, specialists, opportunists, parasites, mutualists, and commensals that includes:

- (1) Documented speciation includes >33 taxa that are cryptic, taxa that are hard to separate out based on physical characteristics. In parentheses are the numbers of other taxa thought to have originated from physical separation of populations (>119), ecologically separated in the same place (>140), and limited gene flow in caves (>25), on mountains (>104), and in soils (>195). There are other ecogeographic speciations that range from the postulated originations of several superfamilies to dozens of underground fungi to thousands of varieties of plants and animals spurred by an increasingly intense Mediterranean climate of dry summers and wet winters that has produced >28 taxa. Toxic soils and increased drought from this climate change decreased woody diversity. However, in a process known as ecologic release, the reduced competition for sunlight so increased herb species richness that it has more than made up for this loss. Speciation has also been enhanced by dozens of hybrid zones, hundreds of bootstrapping co-speciations, and thousands of ecotones.
- Over 3800 disjunctions larger than the Klamaths occur. Disjuncts occur where taxa are geographically separated even though there are habitable areas for a particular taxa that lie between populations. There are over 100 intracontinental disjunct taxa in Klamath wetlands just from presumed relict distributions or from bird assistance in intracontinental plant migrations. Breaks in the gene flow of >84 taxa and over 4000 taxa at range limits also attest to how a dense array of intersecting habitats has enhanced speciation and/or finely divided niche hyperspace.
- (2) Moderate, seasonal, and soil disturbances that vary the duration and proportion of successional and non-successional ecologic states sufficient for successful colonization. Many migrants come from the region, several oceans and other ranges and valleys, most continents, now vanished land bridges, close to a dozen mini-continents, and at least two supercontinents.
- (3) Havens for three monospecific endemic families, four more widespread monogeneric families, and refuges for at least 106 other relict taxa restricted in geography or taxonomy. This is due in part to low extinction rates afforded by a lack of relatively major and geologically rapid disturbances such as continental scale glaciations, ashfall from supervolcanoes, continental flood basalts, large interior seaways, and/or widespread desertification. A higher habitat density than most anywhere helps to mitigate the negative biodiversity effects of lesser calamities and/or enhance their positive effects.

Charina bottae (rubber boa) belongs to a relict group.

A low extinction, and high migration and speciation sum make the region's cumulative effects of time as prominent if not more so than the effects of the region's dense collection of colliding, overlapping, and intergrading ecosystems that make up its biomes. Thus time added to vertical, east-west, and north-south dimensions of the Klamaths more properly creates a geo-bio region or bioregion rather than just an ecoregion. That the region's processes surpasses many either/or dualities or other conceptual constraints in many sciences form one of region's most distinctive and ongoing traits.

Klamath exceptionalism stands out the most in a global context. The Klamath's sum of different kinds of biodiversity largely depends on the geodiversity of one of the world's oldest and highest densities of ~eight climates and ~17 land masses and seafloors arriving from elsewhere. Within these areas are > 50 types of rock, including hundreds of caves and huge granitoid masses of once molten rock (plutons), and thousands of square kilometers of rarely exposed rock whose soil increases speciation of plants that can adapt to conditions too dry or toxic to most plants. Drainages are in the thousands, and there are uncounted large to tiny springs and faults, where rock may have slid many kilometers or just meters, thus increasing side-by-side sharp contrasts in soils and the effects this has on vegetation.

The province may have had up to 17 cycles of stretchings and fusion from collisions that lead to ever larger land and seafloor amalgamations. Pressure-release melting, dropping heavy minerals, and drawing up less dense melts differentiated the liquids and residues into varied rock types. Water added to rocks left behind morphed peridotite into water-rich serpentine, both rock types with great effects on biodiversity. Melts later crystallized as diorite-like rock typical of land volcanoes but whose big crystals made poor sandy soils on which endemics also developed with little competition. That includes the endemic *Lupinus aridus* var. *ashlandensis*, and members of relict Tetrigidae grasshoppers and Gryllotalpidae crickets that can dig their tunnels in sandy soils.

Seafloors were thrust so deep underground that water squeezed out of them flux-melted basalts like salt on ice. The pressure-release of pull-apart basins and mountains undergoing gravitation collapse also melted rock. Heavier minerals dropped out, leaving melts that solidified as relatively less dense diorite in huge masses known as granitoids.

Like a now taller ice cube pushed deep down and squeezed by collisions, the amount of these less dense rocks added to nearly half a billion years of crustal buoyancy that lies at the heart of Klamath species richness. Despite at least a dozen uplifts and tens of miles of vertical erosion, the Klamaths are rising once again to continue its great diversity of slopes, climates, and soils that are the basis of its biodiversity.

Pull-apart geology can increase caves and buoyant granitoid plutons.

Geography

The Klamath Mountains bioregion makes up a major part of southwestern Oregon and northwestern California, with two prongs bounded in the south by the most expansively defined San Francisco Bay region with the Klamath bioregion extending northward to the city of Roseburg in southwestern Oregon. The Siskiyou are north of the Klamath River and so comprise the smaller part of the region. Therefore most people call the whole complex the Klamath-Siskiyou Mountains or just the Klamaths. Of the Klamath ranges, the Trinities link to the Scott, Salmon, and Marble Mountains. But rivers, climates, rock types, and valleys slice through the mountains. They typify the topography of the region as much as any set of ranges.

Outlined Wilderness Areas with Klamath-Siskiyou. From Dominic DellaSala.

Geology

Buoyant Rocks

The lightweight granitic “roots” of many old mountains have been largely lost to erosion, like a boat no longer rising because so little is left to remove and lighten its load. Most old mountains also have been crowded out by incoming seafloors and land masses and so are now too far away from a coast or are too thin perpendicular to prevailing winds to have much climate variation not determined by elevation. Coastal mountains often lack collisional shortening to have risen high or aren’t broad enough from amalgamated land masses to diversity their climates. Ranges in the Americas are mostly aligned north to south, thus receiving similar precipitation and evaporation rates on mostly east and west facing slopes.

Cryptocercus: Appalachian and Pacific Northwest relict.

Based on fossils of some of the world's earliest animals, the Klamaths contains what may be America's sediment. Many parts of the Klamaths traveled across a universal ocean larger by far than half the planet's surface, one that had many more seafloor plates to build and shape a superterrane than is the case for any ocean today. Sideways collisions between lands and seafloors split open basins. Fast sinking seafloors also stretched the crust, moving rocks and their melts up from tens of miles deep far more often than most any other province. Collisions from massive mini-continents, oceanic plateaus, and mid-ocean ridges shoved these heavy rocks on top of Earth's crust and greatly shortened it, uplifting the Klamaths like a squeezed ice cube now floating higher in liquid.

Multiple sunken seafloors, collisions, uplift after dense parts fell off, and subsequent gravitational collapses also have made the Klamaths unusually broad for a province still close to a coast. Many of these crustal movements have changed in speed or intensity in the last 150 million years compared to perhaps thinner crusts and hot and slipperier mantle rock beneath them in older times. The Klamath's great age thus may be a clue as to why in part the bioregion appears exempt from the patterns of most American mountains. In essence, the mold is broken and such terranes aren't made anymore.

Collisions tilt seafloors and shorten buoyant crust, causing uplift.

Coastward Continuance

A province so old is more likely to have a multitude of geologic forces acting on it that makes it differ from the location, height, and orientation of younger mountain systems. While the Sierra and Blue Mountains were pushed inland by thick rock plates, a hot, thin, and bendable ocean floor may have slid under the Klamaths, leaving it near the climate diversity of coastal areas during dinosaurian times (Ernst, 2013). The Klamaths and Sierra Mountains then moved in opposite directions wedged open by an expanding inland sea that eventually drained, creating the Great Valley of California. Like a door opening, greater movement in the south caused the Klamaths to twist.

The Sierras moving northward and a sideways collision with an oceanic plateau (Siletzia) added to this rotation by tilting the Klamaths. Caught between the Pacific Ocean and continental plates, the Klamaths were rolled between sideways sliding faults that were cousins to the San Andreas. Most or all of these motions would have rotated the Klamaths clockwise, causing the ranges to lie aslant of the normal pattern of most American mountains running north and south (Alt and Hyndman, 2016).

Climates

As with serpentine, the Klamaths have a broad Goldilocks' "just right" climatic diversity. Coastal mountains to the north ("mostly wetter") or south ("mostly drier") don't add nearly as much to their own climatic diversities as does the west to east and southwest to northeast directions of the Klamaths that may funnel precipitation into some areas but not into others.

Climatic diversity allows species to escape regional or global extinction by rapidly accessing refugia during climate change. For example, some 40 Klamath near-endemic vascular plants have dozens of sites in the bioregion but only one to five sites in the Sierras and a few sites in other nearby ranges, all areas without the high density of varied refuges that the Klamaths offers.

Little Kerby Peak overlooking Illinois Valley.

Biology

Overview

The Klamaths are the wetter part of the California Floristic Province (CFP) which stretches from southwestern Oregon to northern Baja California and from the coast east to the Sierras. It is defined by a winter-wet, summer-dry climate like that in the Mediterranean Basin. It boasts a species richness of > 5500 native vascular plant species with about 1800 endemics. Just the Klamaths alone have a total of about 192 vascular plant endemics with ~ 28 near endemic taxa having the most sites in the bioregion but which are also found in fewer sites in the northern North Coast Ranges (NCR) down to Clear Lake. The number of strict endemics is more than one would expect as the Klamaths is only about 8% of the CFP.

The CFP is one of the richest floras on the planet, a place where low extinction rates have been more important than either migrations or speciations in determining biodiversity. This is especially true in the Klamath section where old floras and faunas survive due to more abundant precipitation and more equable and stable climates than in the rest of the CFP ([Lancaster and Kay, 2013](#)). Of all parts of the CFP, only an area east of Los Angeles in the rain shadow of the San Bernardino Mountains and with a great variety of elevations is there a higher density of endemics.

Based on known sites and suitable habitat, about 40,000 insects, arachnids, and other arthropod species live in the region. That compares to the 50,000–70,000 species thought to be in the mountains of the Pacific Northwest ([US Geological Survey, 2015](#)). There are hundreds of hybrid plants and at least 23 endemic species apparently created by hybridization.

Biodiversity Behemoth

Aside from a Mediterranean or other temperate peak in diversity in vascular plants and stoneflies, water and carabid beetles, and other groups far from the equator, one can point to other taxa with high diversity. Of the ten mollusk provinces in the United States, three intersect in the Klamaths, the most of any US bioregion ([Burke, 2013](#)). Sciomyzidae and tipulid fly diversity is highest in northwestern California. More reptiles and amphibians inhabit the Klamaths than any other Far West range. Fish species in the Klamaths and Modoc Plateau is only exceeded in the United States in the Southeast ([Allister et al., 1986](#)). Crane fly diversity is higher than in any other Western state ([Alexander, 1967](#)). Compared to other areas of the Nearctic, the ancient Blephariceridae (net-winged) and Deuterophlebiidae (mountain) midges and several ancient spider families each appear to have an endemic peak in the Klamaths.

Of all conifers west of the Rockies, over half are in the Klamaths. With some 3500 vascular plant species in the Klamaths, there is expected to be over 6300 species of macrofungi. Presumably due to a slowly drying climate, hypogean fungi are especially diverse with 44 species in just one genus, 24 in another, and up to five endemics. One small Klamath watershed has more than a third of all known Pacific Northwest lichens in an area comprising $< 1\%$ of Oregon. Just the Oregon part of the Klamaths holds nearly a quarter of all bryophytes north of Mexico ([Villegla et al., 2013](#)).

Relicts

Due to ancient and extensive serpentine soils toxic to most plants, and an abundance of north-facing slopes at mid-elevations, serpentine obligate, boreotrophic, and other relicts total up to one of the three greatest concentrations of paleoendemics Far West

bioregions. Limnanthaceae (meadowfoam), Ascaphidae (tailed frog), and Trilliaceae (trillium) families may have originated here even though some of their descendants are now more widespread.

Taxa starting in the Klamaths also may include two superfamilies of millipedes and spiders, three families of spiders and millipedes, one of fairy shrimp and water mites, and genera of flowering plants (*Phacelia*, *Perideridia*, *Downingia*, *Vancouveria*), heathers (*Pyrola*, *Kalmiopsis*, *Darlingtonia*), true lilies (*Hastingsia*, *Calochortus*, *Camass*), asters (*Tracyina*, *Psilocarphus*, *Wyethia*), and saxifrages (*Bensoniella*, *Romanzoffia*, *Fragariopsis*). Perhaps the world's first spruce, Brewer spruce once lived in much of the West but that range has shrunk to a small part of the Klamaths ([Ledig et al., 2005](#)).

Picea breweriana: endemic relict.

Centers of Diversity

Animal genera with centers of diversity include seven spiders (*Aptostichus*, *Calymmaria*, *Hesperocranum*, *Antrodiaetus*, *Liocranoides*, *Tenggella*, *Titiotus*), three water mites (*Scutolebertia*, *Cyclothyas* and *Siskiyouthyas*), a beetle (*Pinodytes*), katydid (*Idionotus*), hypogean fungi (*Balsamia*), and shrub (*Amelanchier*).

Certain Klamath endemics may be clades of Ericaceae, Taxaceae, *Arabis*, and Saxifragaceae), complexes (*Smilax*), lineages (*Manzanita*, fire-adapted *Pinus*), sections (*Prunus*, *Allium*, *Sedum*, *Quercus* white oaks), series (*Iris*), subgenera (*Fritillaria*, *Penstemon*, *Arnica*), subsections (*Rhododendron*), subspecies (*Pinus balfouriana*), tribes (Cleomaceae) and subfamilies of Scrophulariaceae, Alliaceae, and Agavaceae.

Sadler oak, 1st white oak?

Refugia

Even small areas can provide both refugia and speciations. With northern taxa protected from drought and southern taxa from freezing, certain beetles in caves (*Pterostichus*, *Pinodytes*, *Catoptrichus*), diplurans (*Occasjapyx*), grylloblattids (*Grylloblatta*), harvestmen (*Taracus*, *Sabacon*), crickets (*Pristoceuthophilus*), pseudoscorpions (*Pseudogarypus*), and spiders (*Calymmaria*, *Cybaeus*, *Pityohyphantes*) may have had a long time to speciate at the edge of their ranges as they often belong to relict or other ancient groups. Serpentine patches extend northern range limits in which budding speciation may have produced new *Salix* (willows), *Silene* (catch-flies), *Erigeron* (fleabanes), *Sedum*, *Kalmiopsis*, *Boechera* (rockcresses), and *Calochortus* and *Hastingsia* (rush) lilies.

Kalmiopsis.

Like caves, coastal areas, and north facing slopes at mid-elevations, the refugia-within-refugia of running water (fens, hyporheic, springs, rivers, streams), and bogs, deep groundwater, and vernal pools tend to have low extinction rates by virtue of species being largely protected from hard freezes or severe drought. These habitats contain some of the oldest families, including those of frogs (Ascaphidae), fishes (*Petromyzon*, *Acipenser*), flies (*Deuterophlebia*) and beetles (Amphizoidae), and three Klamath near-endemic mite genera.

Other ancient aquatic or partly aquatic animals include certain bryozoans, crane flies (*Pediciidae*), crustaceans (Notostraca, Anostraca, Mysida, and Conchostraca), syncarids (*Pacificabathynella*), dragonflies (Petaluridae, Gomphidae), hydrozoans (*Hydra*, Hydrozoa), mayflies (Ephemerellidae, Siphonuridae), fishflies (Corydalidae), and sponges (*Spongilla*). Water-loving archaic groups include certain ferns (Blechnaceae, Osmundaceae), herbs (*Aristolochia*, *Anemopsis*, *Aralia*), waterlilies (*Nuphar*, *Menyanthes*), skunk cabbage (*Lysichiton*), hornworts (*Ceratophyllum*), horsetails (*Equisetum*), quillworts (*Isoetes*), and pitcher plants (*Darlingtonia*).

Darlingtonia.

Some old groups are not strictly aquatic even in their juvenile stages but they do rely on abundant water. Due to primitive kidneys that poorly conserve water, the relict monogeneric Aplodontidae (mountain beavers) feed mainly on succulent vegetation and burrow in moist soils. Single cell cercozoans who live in damp cave soils are related to the much larger foraminiferans that form much of the limestone of the pyramids. Shasta Springs has even less acreage than riparian or coastal areas. This thermal refuge within an aquatic refuge probably dates to about a hundred million years ago though the centipedes (*Kiberbius remex* and *Nadabius oreinus*), springtails (*Microcreagris magna*) and diplurans (*Haplocampa wheeleri*) only found there may be relatively new.

Other ancient groups not aquatic include lizards (Anguidae), diplurans (Japygidae), spiders (Mygalomorphae, Pimoidae, Lep-tonetidae, Anapidae, Hypochilidae), pseudocentipedes (Scutigereidae), harvestmen (Sironidae, Triaenonychidae), proturans (Acerentomidae), roaches (Cryptocercidae), and springtails (Neelidae). Ancient plant groups include certain families of club mosses (Lycopodiaceae) and conifers (Pinaceae, Cupressaceae), and genera or lineages of flowering trees (*Quercus* white oaks, *Platanus*, *Salix*, *Rhamnus*, *Staphylea*, *Betula*, and *Juglans*).

Endemism

Prior to over 34 million years ago, at least several hundred genera of plants and animals had come to the Klamaths. As climates cooled and dried they became more restricted in their geographic range or they became extinct. Many still inhabit north-facing slopes at moderate elevations, places neither too cold nor too dry and thus similar to the semitropical habitats of the boreotropics that once stretched across the northern hemisphere. Not only did such slopes offer refugia but they may have been centers of isolation-speciation as well, with about 81% of Klamath endemics found inland versus endemics or near-endemics from more coastal sites. Part of the reason for this likely is because near-coastal areas are closer to the Klamath boreotropic climates than mid-elevation slopes further inland.

However, the reduced area and increased competition in coastal areas compared to other refugia lessened biodiversity. Trees and shrubs likely have suppressed herbaceous plant speciation and/or increased extirpations while the ease of low elevation migrations along the coast has reduced the number of narrow endemics. Consequently, compared to inland areas, only about 6% of Klamath plant taxa are shared with the adjacent coast as near-endemics (~13 vs. 188 taxa). About half of ~633 Klamath animal endemics or near-endemic species are shared with the coast, indicating that more animal endemics have originated from near-coastal montane genetic isolation and/or more taxa have been preserved by coastal climate buffering than is the case with plants shaded out by competitors.

The numbers and distribution of taxa suggests that the Klamath's mid-domain location enhanced biodiversity before and after its terranes had been sutured together with granitoid stitching plutons. Generally from the most to the least, prehistoric emigrants above the level of species include those from Asia (>230 taxa + >15 Himalayan taxa), South America (>120), three supercontinents (>21), and Europe (>11 + >9 Mediterranean and 7 Caucasus regions). Most of these Klamath taxa are now disjunct from relatives living in postulated origination areas.

Compared to genera native to North America, fewer of these genera and those emigrating to other continents gave rise to two or more Klamath endemic species (~22 vs. ~48). Apparently the high mobility advantage of most migrators moving in from various intercontinental directions increased gene flow. Thus reducing the likelihood of speciation. Instead, many endemics may have come from Klamath or nearby areas, places where genetic divergence may have been initiated by disturbances, geographic barriers, or ecologic release. Klamath/Sierran and mid-continent seaways may have helped diverge more than ten species while a meteorite impact may have fragmented the populations of >38 species. Even hitchhiking on birds may have separated >144 species on opposite sides of the continent. Post-uplift drought and increased climate seasonality may have helped to fragment populations, with the resulting genetic separations perhaps leading to >408 species.

More migrations from other regions and a moderate climate lessened extinctions and extirpations near the coast. There Klamath near-endemic plants derived from genera thought to have emigrated from other continents rises to about half of those thought to be derived from native genera (68 vs. 133) (Harris et al., 2013). Due to the even greater intercontinental mobility of animals, including many if not most Klamath endemics, there is an evening of the emigrant/native taxa ratio at ~322 vs. ~322.

Serpentine

Of all rock groups, serpentinite and peridotite have the greatest effect on biodiversity and speciation. Klamath serpentinite beds have been less tilted and more duplicated and stretched by faulting than serpentinite in the California Sierras or Oregon Blue Mountains. This produces wider and greater numbers of serpentine belts in the Klamaths. Unlike the Sierras and Blue Mountains, Klamath serpentine soils derived from a more even mix of peridotite and serpentinite. This adds to microhabitat diversity due in part to peridotite shading and runoff from its boulders. In other words, a more diverse microtopography shelters a greater diversity of plants in this rock type compared to the number of species in more topographically uniform, barren-looking soils derived from serpentinite.

Serpentine: rare rock elsewhere but common in Klamaths.

The percentage of serpentine endemics is way out of proportion to the area of serpentine. Endemics make up about 10% of the CFP vascular plant endemics yet serpentine soils in California comprise <1% of the state's surface. The ratios in the Klamaths are even more lopsided as serpentine covers about 14% of its land area, perhaps the most of any bioregion in the world. As a result, of all Klamath near-endemics shared with the NCR, ~191 taxa or 87% have serpentine affinities.

California plants on serpentine in relatively moist sites common in the Klamaths are more diverse in function and genetically more different from each other than those on drier sites (Anacker, 2011). This also indicates a low Klamath extinction rate and thus a long enough residence for plants to become neoendemics or even paleoendemics or relicts or both. The high evenness of microhabitats and the sheer areal cover of serpentine areas of the Klamaths also reduces the likelihood of developing a biologic sink in which species become extinct. As a result of differential extinction, speciation, and migration rates, there are about three times more plant taxa entirely or largely confined to serpentine in the Klamaths compared to that of any other region in North America (Coleman and Kruckeberg, 1999).

Peripheral speciation at the southern end of the Klamaths may have also played a role in boosting biodiversity. If so, then a greater net migration from a Klamath source to the northern NCR may have helped result in producing ~28 shared near-endemic species. In contrast, the southern North Coast Range (sNCR) has fewer shared near-endemics (~15 taxa) and less areal exposure of serpentine soils and is further away from most potential near-endemic migrants.

There's not only a north-south difference in serpentine obligates. There are fewer serpentine-dependent taxa in coastal areas compared to more inland areas, a pattern that may be due to higher species competition. Fewer serpentine species in the Sierras compared to most of the Klamaths may be due in part to more drought extirpations. There also are fewer endemics in both areas compared to the Klamaths, in part because of fewer and geologically more recent serpentine outcrops.

Being close to the birth of seafloors allowed the still heat expanded and so light enough oceanic slabs to be pushed on top of the Klamaths. These collisions were so strong that seafloor sequences were fault duplicated and preserved rather than sinking back down below Earth's crust. The Klamaths thus are in a not-too-wet/not-too-dry, just right Goldilocks zone of many ancient and isolated serpentine areas conducive to speciation and much larger areas of continuous serpentine that reduces extinction rates (Harrison et al., 2004).

Serpentine soils also impact fungal diversity. Out of 14 endemic or near-endemic peas, only four can tolerate serpentine, most likely because of its toxicity to many of their symbiotic root fungi. This intolerance to certain heavy metals and/or a high magnesium to calcium ratio may extend to other fungi as there are no mushrooms with fruiting bodies that are known only from Klamath serpentine. However, 32 of 74 ectomycorrhizal fungi associated with Garry's oak (scientific name) were unique to serpentine soil (Moser et al., 2005). Such underground fungi mostly fruit in the spring and so are not as dependent on a moist fall to ensure spore dispersal, as are most above-ground fungi.

Calcite

Though rare, calcite rocks and their soils host about half a dozen flowering endemics, several hypogean fungi, a possibly new species of moss, dozens of snails, and at least ten lichens largely or wholly restricted to marble or calcium rich springs. The Hosselkus and McCloud rock formations alone have four endemics among *Erythronium*, *Adiantum*, *Ageratina*, and *Neviusia*, as well as a snail and

three salamander endemics, and, according to one botanist, an “outrageous shrub diversity.” Leaf-wise, the calcite endemic *Neviusia* has a virtually identical species that dates back to the boreotropical era. The closest relatives of the *Batrachoseps* salamanders may be in Korea (Vieites et al., 2011), suggesting that the genus also is relict.

In contrast, the Scott Bar’s salamander’s (*Plethodon asupak*) geographic location and genetic closeness to the endemic Del Norte salamander (*P. elongatus*) suggests it’s a neoendemic that separated from the older species at the edge of its range. This evolution, known as budding speciation, may be very common in the Klamaths, given the large number of range limited species. It is less dependent on soil types than is the speciation of serpentine plants, although caves and sandy soils can also increase the range limit and hence geographic separation of animals and plants, rendering them more likely to become isolated from larger populations and develop into new species.

Soils

Not only are Klamath rocks exceptionally varied with unusual percentages of normally rare rocks, their debris is even more so as its soils track the most varied of climates in time and space with some of the world’s shortest geographic distances between climates. Due to multiple uneven uplifts and thick layers of tilted and varied bedrock rare elsewhere, a great range of soils have been relict from past climates, including extensive areas of iron-rich lateritic soils formed in tropical times near sea level. Based on woody plant diversity, a high density of soils/climate interactions sustained cradles of creation and museums of Klamath biodiversity for at least 16 million years (Barnett, 2008). Fossils indicate that in an area known as the Far West (Alaska to California), at least 107 genera (> 90% woody spp.) from these times became extinct or extirpated largely due to increasingly drier summers and/or colder winters. However, reduced shading competition likely sped up speciation of thousands of herbaceous plants.

Fire Influences on Plant Diversity

Frequent fires of varying intensity, the unusually diverse mix of hardwoods and conifers, and a moderate variation in climates may prevent single vertical plant levels from dominating as they do in more extreme conditions in tundra, coastal savannas, and grasslands respectively to the north, west, and east of the Klamaths.

Multi-level canopies or other structural complexity can increase the species richness of certain mammal, bird, lichen, and arthropods. The diversity of galls made by nematodes, flies, mites, moths, and gall wasps may exceed that of most other mountains. Klamath gall-making houses thousands of species including three Cynipidae wasps, one Cecidomyiidae midge, and one Cosmopterigidae moth, all regional endemics or near endemics because they live as larvae on trees or shrubs endemic or near-endemic to the bioregion.

A dense set of habitats greatly varying in moisture and slope steepness builds biodiversity via bootstrapping in part by allowing or enhancing a variety of fires in their intensity, frequency, and coverage. That is in part because fires that reach a habitat different from where it started will often change in intensity, rate of spread, or even die out altogether due to sharp geographical contrasts in fuel loads, soils, and slope gradients. This fine-grained variation in habitat and the resulting patchy nature of fire and its severity favors the ecology of fast-reproducing migrants in some cases and genetic diversification of those not so mobile in others.

In particular, mixed-severity fire regimes common in the Klamaths likely increases resilience, an ecological “bounce back” so that even local extirpations are few, thus promoting diversity on regional and local scales especially in disturbance-adapted riparian zones, savannas, and oak woodlands. Similar to how evenness of species populations tends to maintain biodiversity, more or less equal proportions of different habitats shaped by fire frequency, intensity, and duration or its absence is a pattern most likely to prevent regional or even local extirpation due to close by areas that have suitable habitat for migrants looking for a new home. Fire may most benefit specialized hemiparasites and predators among plants in serpentine fens, such as *Castilleja* (paintbrushes), *Pinguicula* (bladderworts), and *Darlingtonia* (pitcher plants).

Conservation

Tools to restore or maintain biodiversity and the ecosystem services they provide include managed and let-burn fires, including wildfires across a range of size and fire severity, prescribed burning, and variable density thinning. All are ways that can help match prehistoric-like climate variation in sites, snowpack, and disturbances and their effects on ecological resilience, and distribution and richness of species, including birds and mammals. Removal of invasives and/or increasing resistance to homogenizing monocultures can also help restore native biodiversity in certain amphibians, bats, microbes, and birds.

The nearest relative to the tailed frog depicted here is in New Zealand.

Judicious use of hands-off management, manual fuels reduction, and prescribed fire that best matches the effects of prehistoric fires can prevent encroachment of conifers into oak woodlands and fens, preserve ponderosa forests, and prevent shading out of shorter trees such as madrones. Thinning of <8 in. diameter trees can improve drought and fire resistance although competition by exotic species, fire suppression, and limited funding confounds attempts to accelerate old-growth traits in second-growth forests. However, even small scale efforts can heighten biodiversity in arthropods, butterflies in particular, and strengthen vegetative resilience in oak woodlands.

Provided there's substantial mitigation of the decline in biodiversity from the effects of non-natives, old-growth reduction, and extremes beyond the intensity, frequency, and/or range of climates in the last 11 millennium, the Klamath bioregion will continue to be a refugia for genetic diversity at all levels by continuing ecosystem services for natives and for arguably its most key non-native. Given these protections, the bioregion will retain its outstanding density of microrefugia at certain elevations for many species (Olson et al., 2012; Harrison and Noss, 2017). North-facing slopes at mid-elevations may offer refugia to some species during rapid warming and are likely to be less affected by anthropogenic change than is the case for other elevations. This contrasts with subalpine plants that may be subject to the competitive exclusions of taller growing plants benefiting from longer growing seasons. Taxa at lowland areas may be lost from extreme multi-year droughts or a higher rate of other human disturbances.

In support of the latter effects, relatively low elevations are where endemic Klamath taxa once lived but likely are now extinct. These may include a *Fluminicola* undescribed snail species, two popcorn flowers (*Plagiobothrys lithocaryus* and *P. lamprocarpus*), two caddisflies (*Rhyacophila amabilis* and *Agapetus denningi*), and two mariposa lilies (*Calochortus monanthus* and *C. indecorus*).

Increased regeneration of aspens, bird diversity, early seral mixed hardwoods, flowering species migrating from the south, and butterfly diversity will increase under most climate change scenarios. This would require that forest openings and the vertical structural diversity of tree canopies be maintained through mixed severity fire regimes, subalpine areas be protected from tree encroachment, and human impacts like overgrazing and off road traffic be contained and/or minimized. Based on numerous studies on climate change, many aquatic taxa will increase with the anticipated greater increase in broadleaf forests and their arthropod associates, provided that water and air quality and quantity can be maintained or improved.

Education of decision makers, general public, and politicians can heighten commitment to preserve intertwined biodiversity and ecosystem services, especially in biodiverse but still poorly understood areas like the Klamaths. However, such education must convince most human stakeholders that species richness contributes to services on a much broader and in depth scale than what has been understood so far. We have barely begun but we now know from many sciences what most cultures knew for millennium, that contact with the wild keeps us healthy on immune, cognitive, empathic, communal, evolutionary, and spiritual levels. Learning or remembering to appreciate the reciprocity of this mutual flourishing is a necessary step in attaining sustainability at all levels as we only protect well that which we love.

Wood eating fungi.

Abstract

From the Bronze Age the increase of human pressure such the livestock farming, crops harvesting, forests exploitation and the coming of the widespread urbanization, after the Roman Empire, have intensely transformed the woodlands in the Mediterranean basin. Mediterranean landscapes are profoundly different from the original ones prior to large-scale human degradation. The vast impenetrable forests have mostly been replaced by fragmented patches and by a sparse vegetation. Nevertheless, it remains a biodiverse landscape where waves of colonization left remnants of original forests that can provide clues for restoration of Mediterranean evergreen oak forests.

Mediterranean Forest Types

Broadleaved evergreen forests dominated by sclerophyllous oaks (*Quercus ilex*—holm or round-leaved oak, *Quercus coccifera*/*calliprinos*—kermes/palestine oak, *Quercus suber*—cork oak) are essential elements in the assessment of the Mediterranean forest ecosystems. These oaks aggregate form a zonal forest belt around the coastal districts of the Mediterranean Sea with only one large gap in N Africa, from Libya to Southern Levant, and with the sole exception of a small isolate in Cyrenaica (see Fig. 1).

Stands of broadleaved evergreen forest are also spread inland in the Atlas mountains, throughout the nearly whole Iberian peninsula (except for its N Westernmost coastal districts), south France (from Provence to the west side of the Central Massif and the Aquitanian coast), peninsular Italy (up to middle altitudes), southern and Aegean Greece and islands and from western and southern Anatolia to the mountains of Lebanon. They remain confined close to the coasts in northern Italy, Dalmatia and southern Palestina.

Together with the dominant oaks, an array of evergreen woody, mostly sub-arboreal species can be found: *Laurus nobilis*—bay laurel, *Myrtus communis*—common myrtle and *Viburnum tinus*—laurestine are the most common. Although numerous studies have investigated the structure and function of this ecosystem, the definition of the typical plant assemblage of Mediterranean forest has been quite ambiguous or unclear throughout the history of European plant ecology.

The classic Mediterranean landscape has been perceived and celebrated as the realm of a snuggled twisted scrub, with few scattered low trees, at least from the time of the “Grand Tour” onwards (Black, 2003), be it rich of suggestions and hints to the pastoral, fragrant landscape of an idealized classicism or biblical world (see Figs. 2 and 3). This interpretation was accepted in the scientific debate, focusing on a very widespread, changing, species-rich vegetation mosaic of treelets, low, woody shrubs, and open patches with dwarf shrubs with species from genus *Arbutus*, *Phillyrea*, *Rhamnus* *Erica*, *Pistacia*, *Myrtus* etc. as standard and ultimate elements in the structure of this vegetation.

Its original structure of almost closed and high, non-fragmented forest, dominated by evergreen oaks, has been widely ignored. The heavy impact of human disturbance, since the onset of the agro-pastoral colonization of the Mediterranean coastal regions (8–6 Millennium BP), through the degradation inducted by tillage, anthropogenic fires, charcoal processing, forest grazing, turned this forest vegetation into that celebrated, iconic shrubland called “Macchia” (in Italian for “coppiced stools”, copses) or “Maquis” (in French). For a long time, these woodlands have been erroneously considered a kind of zonal, structurally stable, representative plant cover of the Mediterranean landscape. The famous botanist and phytosociologist Braun-Blanquet in his pivotal works on phytosociological nomenclature in 1933 and 1936 stressed the structure of the Mediterranean evergreen forests as zonal, late successional association of evergreen sclerophyllous woody species (*Quercetum ilicis galloprovinciale*). From this moment on, its status as a forest biome began to be acknowledged by researchers. Up to the middle of the 20th century, *Q. ilex* and even more *Q. coccifera* were considered shrubby oaks, small to medium-sized, long-living trees and only exceptionally large trees (Giacomini and Fenaroli, 1958; Pignatti, 1979). Most of the known location throughout the Mediterranean region were degraded to pastured woodlands or were coppiced at short time intervals due to their nearly unailing capacity of resprouting.

Fig. 1 Distribution map of evergreen oak woodlands in southern Europe and northern Africa, according EUFORGEN maps (see <http://www.euforgen.org/species/>), European Vegetation Archive (<http://euroveg.org/eva-database>; Chytrý et al., 2016) and references (e.g., Caudullo et al., 2017).

Fig. 2 The coastal landscape of Tuscany (Italy), the evergreen oak forest. Photo by Emiliano Agrillo.

The general reduction of coppicing in the Mediterranean countries during the last hundred years, or the much longer clearing intervals (in terms of cycle length), induced an overall transition from scrub to forests. This process is now active on vast areas and is ensured by conservation measures and directives, at least in Europe (e.g., the “Habitats” Directive 92/43/EC). *Quercus ilex*, reveals in mature present day stands (e.g., Tyrrhenian Italy) the crown habit and architecture of a tall, late-successional tree adapted to closed, dense canopies more than any other deciduous or evergreen Eurasian oaks. This species is also capable of active seed regeneration in the nearly dark light conditions of the forest floor. *Q. coccifera/calliprinos*, also long considered a shrub or a lower

Fig. 3 Holm oak and cork oak forest (Central Italy). Photo by Emiliano Agrillo.

treelet, in Crete and Anatolia (Jalas and Suominen, 1988; Vogiatzakis and Rackham, 2008) is often a real tree, attaining 20 m tall as relic of former now disrupted forest stands. The ultimate rehabilitation of its status as representative of the Eurasian evergreen broadleaved forest biome, is due to the works of Specht and Moll (1983) and Mai (1989).

Sclerophyllous Forest Distributions and Patterns

The distribution pattern of the three main taxa of the sclerophyllous forest is highly explanatory. A major distinctive character in the structure is the dominance and spread of *Q. ilex* in the W part of the Mediterranean region (N Africa, Italy, Iberia and France where it reaches the Atlantic coasts). East of the longitude of Rhodos and Northern Caria in W Anatolia, *Q. coccifera* becomes the only arbo-real representative of this evergreen broadleaved sclerophyllous forest, as well as in the Cyrenaican isolated enclave. Quite rare and scattered in the Central Mediterranean region (SE Italy, S Sicily and SW Sardinia), this oak conversely becomes very common again throughout the Atlas, S and E Iberia and Provence, thus displaying a nearly bipolar Mediterranean range (Fig. 1). *Q. suber* has the bulk of its range centered in the westernmost Atlantic districts of the Iberian Peninsula (see Agrillo et al., 2018), as well as in the Atlantic districts of Morocco, reaching the Tyrrhenian islands (Balearic Islands, Corse, Sardinia and Sicily) and the coastal fringe of Western Italy. It becomes extremely rare already in the Adriatic districts, with a few scattered stands in SE Italy (Apulia) and N Dalmatia where it occurs in a few locations, more often as hybrid populations (*Quercus crenata*—false cork oak) with its deciduous, temperate, subcontinental relative, *Q. cerris*—Turkey oak. Outside the SW Iberian core area, *Q. suber*, among the mentioned oaks, exhibits the most fragmented and discontinuous range.

All three taxa converge, coexist and cover their largest expanses in the Western Mediterranean region with Iberia and Morocco as core areas. Particularly intriguing is the occurrence of *Q. suber* disjunct stands along the Atlantic coast of Central France, where *Q. ilex* even reaches the Bretagne region (i.e., N Aquitania, Ile de Noirmoutier). The species exhibits scattered and rare populations along the coasts of the Black Sea of N Anatolia, long outside its zonal range.

This complex pattern, better than any other parametrization, synthetically outlines the different individual ecological demands among the species of oaks of the Mediterranean evergreen oak woodlands and sheds light on their developmental history.

Considering a global gradient of increasing xericity from W to E from the Atlantic coast to the Levant and the subordinate superimposed effect of more mesic macroclimatic conditions at the Western sides of any of the Mediterranean peninsulas. A rough outline of their basic requirements puts *Q. suber* at a warmer and moister side of a macroclimatic gradient. *Q. coccifera* is at the warmest and driest end (districts in the Ebro valley experience dry, nearly semidesert conditions), while *Q. ilex* apparently occupies an intermediate, alternatively more eurieious, position shifting towards the cooler end of the gradient in the oaks.

An amount of lower taxonomical rank has been suggested throughout the ranges of these oaks. Hybrids, introgressions, different interpretations of the same species by different authors, with an often-emphasized endemic character, have been asserted and proposed during time, neglecting the effect of phenotypic plasticity in species scattered along gradients of high environmental heterogeneity.

Major differentiations within *Q. ilex* might occur in the Iberian Peninsula and throughout NW Africa to Algeria (up to 2200 m a.s.l.). Here a very closely related taxon (*Q. ballota*) is reported as vicariant, coexisting with *Q. ilex* only within a narrow fringe of the Cantabrian coasts of N Spain and all along the E coasts of Spain. Within the *Q. coccifera* circum-Mediterranean species

complex, differences are even more indistinctive and clinal. The latter might merely be a more xerotolerant and eastern morphotype of the former, with denser hairiness on the younger shoots, reported from N Algeria, the SE coasts of the Italian Peninsula, to Turkey, Cyprus and further East to Palestina.

A closely related *taxon* to *Q. coccifera*, *Q. alnifolia* is known for its densely golden or brownish tomentose leaves below, and is endemic to Cyprus (Barbero and Quézel, 1979). *Quercus aucheri* (*Q. coccifera* sub-species *aucheri*) strongly pubescent, a dubitative distinct species (Toumi and Lumaret, 2010), is reported from the Aegean island of Cos and in the district of Istanbul.

In fact, *Q. coccifera*, *Q. calliprinos*, *Q. aucheri* and *Q. alnifolia* are apparently part of a very variable but genetically indistinguishable complex (Denk and Grimm, 2010) with its highest morphological diversity in the East. Additionally, all the western Eurasian *Ilex* oaks (*Quercus* subg *Sclerophyllodrys* sensu Schwarz 1959; *pro parte* subgenus *Cerris* sensu Denk; *Quercus alnifolia*, *Q. aucheri*, *Q. coccifera* and *Q. ilex*) are resolved as a monophyletic group (Denk and Grimm, 2010). These representatives of intriguing episodes of the evolutionary history within the *Cerris* group (sensu Denk and Grimm, 2010), suggests persistence of a higher degree of relictuality in the East, in the peri-Anatolian area for the xeric representatives.

In the W, more common are interspecific hybrids both among the evergreen and submediterranean deciduous or semi-deciduous oaks. The following taxa are reported: *Q. x airensis* (*Q. ilex* x *Q. coccifera*) in France, Spain, Portugal, Morocco, Algeria, Sicily, Greece); *Q. x autumnalis* (*Q. ilex* x *Q. rotundifolia*) in Spain; *Q. x mixta* (*Q. ilex* x *Q. suber* = *Q. morisii*) in France, Spain, Portugal, Italy, Sardinia, Sicily, Algeria; *Q. diosdadoi* (*Q. pyrenaica* X *Q. rotundifolia*) in SW Spain (Extremadura); *Q. x senneniana* (*Q. faginea* x *Q. rotundifolia*) in N Spain; *Q. afares* (*Q. canariensis* X *suber*) in North Africa (see Barbero et al., 1992), suggesting at least higher evolutionary dynamism for the more mesophilous representatives in the W.

Climatic Effects on Evergreen Forests

Traditionally, evergreenness in the Mediterranean oaks and their associates are assigned to a fundamental adaptation to the ruling Mediterranean-type climate of the region. They are characterized by summer drought, winter rain of cyclonic origin and mean annual temperature of $15 \pm 5^\circ\text{C}$. This trend recurs in other parts of the world at around 35 degrees latitude, where ruling actualism in geobotany strongly emphasizes the occurrence of physiognomically and adaptive similar, convergent forms of vegetation (American chaparral, S African fynbos, Australian mallee, Chilean matorrales). This pattern attracted most studies in modern plant ecology (Terradas, 1999).

Evergreen oaks are therefore drought tolerant when compared to the winter deciduous trees of the temperate forests. Summer dry, evergreen forest ecosystems apparently thrive under these constraints. Their species develop thick, leathery, hard-surfaced drought resistant, long living sclerophyllous leaves with waxy coatings, enabling them to withstand water loss during severe summer drought while their evergreen habit enables them to benefit from winter moisture (see Fig. 4 modified diagram; Pavari, 1959).

The rationale of the evolutionary success of the sclerophyllous model characterizing the plant cover in the Mediterranean region is centered around the observed links between the adaptive traits of these oaks, those of their associates and the ruling climate. Nevertheless, their evergreenness is primary in the history of the *taxon* and in the history of most of their woody associates, achieved long before the onset of a Mediterranean type climate in the Old World.

Nevertheless, shifting degrees in Mediterranean evergreen oaks of sclerophylly facing laurophyllly, suggest close phylogenetic relationships with an array of evergreen subtropical oaks of Himalayan or SE Asian range, like *Quercus baloot*—holly oak and *Q. floribunda*—moru oak, a tall tree very closely related to *Q. ilex* (and for some Authors, its Asian form). Also molecular data suggest that *Q. aucheri*, *Q. alnifolia*, *Q. coccifera* and *Q. ilex* share a common origin with the Himalayan *Q. floribunda* and *Q. baloot* (Denk and Grimm, 2010; Simeone et al., 2016; Hubert et al., 2014).

These species, all reaching higher altitudes in W Himalaya (1700–3000 m) and other “ilicoid” oaks (*Q. semecarpifolia*—Brown oak, *Q. leucotrichophora*—woolly oak, *Q. glauca*—blue Japanese oak) belong to the subgenus *Cerris* sensu Denk evolved from an originary, late Neogenic Indo-Malesian stock (Zohary, 1973), close to fossil western Eurasian evergreen macrothermic oak species of late Neogene (*Q. drymeja* and *Q. mediterranea*: Denk et al., 2017).

A geographical continuity in the evolutionary processes of species and ecosystems between the present-day Mediterranean region and the laurel forests of E Asia must, therefore, be postulated. The analogy among the five enclaves of Mediterranean-type ecosystems in the world is probably at least partly misleading when the coenological (i.e., ecological community) history of these formations is taken into account. Indeed, all of them are rather comparable only to the disrupted assessment of the present-day Mediterranean evergreen broadleaved forest biome dominated by sclerophyllous oaks. Late successional recovery of these evergreen oak woodlands should shift the analogies to climatically different regions of the Old World, where the dominant Mediterranean evergreen oaks find their most outstanding aspects of their evolutionary history shared by laurel forest species. The laurel forest of the Canary Islands can provide useful insights in the development of the Mediterranean broadleaved forest biome in the framework of its phylogenetic connections to the E Asian analogues.

Lauroid termo-hygrophilous relic species such as pontic rhododendron (*Rhododendron ponticum*), laurel (*Laurus nobilis*, *Laurus azorica*), Portugal laurel (*Prunus lusitanica*/P. *laurocerasus*), English holly (*Ilex aquifolium*), box (*Buxus sempervirens*/B. *balearica*), mediterranean palm (*Chamaerops humilis*) or myrtle candleberry (*Myrica faya*), are considered a footprint of the disappeared Madrean-Thetyan paleotropical vegetation (Axelrod, 1975; Mai, 1989). Their ancestors were widespread in Paleo-Europe during the warm and humid late Tertiary (Palamarev, 1989). However, several waves of cooling and aridization started at the end of the Paleogene led to the extinction of the majority of the laurophyllous lineages (Barrón et al., 2010; Palamarev, 1989). When

Fig. 4 Environmental and climate gradient belts of Evergreen Oaks forest in the Mediterranean region dominated by Holm Oak.

the present-day Mediterranean climate established (about 4.5 ka B.P.), only a few relic laurophylls persisted within refuges of southern Europe (Axelrod, 1975; Barrón et al., 2010; Suc, 1984). Indeed, many of these relic laurophylls are nowadays restricted to Macaronesia and in the Western Caucasus where the climate is still humid. On the other hand, only a few of them occur in the Mediterranean region, since they are limited by low winter temperature and scarcity in precipitation (Alessi et al., 2019; Rodríguez-Sánchez and Arroyo, 2008). Here, relic laurophylls occur in extrazonal groves, where micro-topography provides sufficient moisture for their termo-hygrophilous demands (Alessi et al., 2018; Costa et al., 2015). These extrazonal sites act as modern refugia for laurophylls following the latest climatic deterioration (Alessi et al., 2019; Rodríguez-Sánchez and Arroyo, 2008).

The biogeographical history of laurophylls is hence strongly related to that of the Mediterranean oaks and their associated species. The extant evergreen oaks of Europe may have been arisen from the laurophyllous vegetation and its elements (Barrón et al., 2010; Denk et al., 2017; Jiang et al., 2019). Indeed, Mediterranean oaks derive from East Asian ancestors occurring within the Eocene subtropical-tropical forest (Denk et al., 2017; Jiang et al., 2019; Simeone et al., 2018). However, while all of the extant Asian oak species grow today in regions influenced by proximity to monsoon climatic conditions, providing seasonal high amount of precipitations, their closest relatives of the Mediterranean region occur within the drier Mediterranean macroclimate (Box, 2015). Thus, the evolutionary history of the Mediterranean oaks and their ecosystem has been extended far beyond the present-day environmental assessment of Eurasia, in the framework of a completely different paleoecological and paleogeographical scenario (Denk et al., 2017; Jiang et al., 2019).

Habitat Directives for Sclerophyllous Forests

The importance of maintaining this landscape has been recognized by a legal and regulatory framework. The conservation of Mediterranean sclerophyllous forests is ensured in Europe under the application of the Habitats Directive (92/43/EC). Six different habitat types with evergreen oaks (Table 1) are targeted for conservation as listed in Annex I of the Directive (http://ec.europa.eu/environment/nature/legislation/habitatsdirective/docs/Int_Manual_EU28.pdf).

Another important initiative at European level is the Red List of European Habitats http://ec.europa.eu/environment/nature/knowledge/redlist_en.htm. It reviews the current status of all natural and semi-natural terrestrial, freshwater and marine habitats and highlights the pressures they face. Using a modified version of the IUCN Red List of Ecosystems categories and criteria, it covers the EU28, plus Iceland, Norway, Switzerland and the Balkan countries and their neighboring seas. In this List evergreen forests (Table 2) are considered an outstanding example of typical characteristic of the Mediterranean biogeographical region, in terms of area, species composition, structure and functioning. They are recorded under the G2.1 Mediterranean evergreen *Quercus* woodland, with a category of Low Concern assessment <https://forum.eionet.europa.eu/european-red-list-habitats/library/terrestrial-habitats/g.-forests/g2.1-mediterranean-evergreen-quercus-woodland>.

Conservation Challenges and Threats

Whereas in the past there still lasting natural spaces to hosting the iconic species of these forests in a proper viable condition, throughout the natural spread in the Mediterranean ecosystem, massive changes in abiotic and biotic condition put this outstanding representative of the Mediterranean Biome under a major threat.

Mediterranean forests are still exposed to serious threats that put biodiversity at risk. Severe fires, degrading land use practices (such as monoculture, plantations of introduced species, excessive grazing) and extensive human pressure (urbanization) exacerbate the already heavy impacts of climate change with scenarios that foresee an increase in temperatures and aridity in the Mediterranean basin.

In fact, the Mediterranean Basin is affected by numerous aspects of environmental change, a combination of changes in land use with overexploitation, increasing pollution of air and water and declining biodiversity. It is one of the most vulnerable regions to the impacts of global warming with an increase of flooding events, heat waves and biodiversity loss anticipated. With increasing aridity, fire risk becomes more frequent. The Intergovernmental Panel on Climate Change (IPCC, 2013) identifies the Mediterranean as one of the region's most vulnerable to the impacts of global warming, nevertheless the effects on Mediterranean evergreen forest are not widely agreed. Since no single climate change scenario for a site/area is likely to be definitive, no human intervention can provide any realistic global counterweight. As long as world vegetation will respond to climatic patterns, changes to plant communities will be, and have always been, implicit in the system.

This appealing phenomenological category and concept cannot be applied to conservation since it implies management actions of far-reaching unrealistic silviculture that will only artificialize habitats by converting them into gardens. In fact, silviculture and afforestation are basically threatening the biogeographical assessment of Mediterranean forests, mainly through active afforestation. Conifer plantations are the best example. Plantations of Mesogean pines all over the coasts and inland warmer sites have deleted natural biogeographical gaps. Moreover, they are likely to have induced dilution or even extinction of local genotypes selected by long term isolation (*Pinus pinea*—Italian stone pine, *Pinus halepensis*—Aleppo pine, *Pinus pinaster*—maritime pine, *Pinus nigra*—black pine). *Abies alba*—a common fir forest—has undergone the same destiny. Silvicultural practices may also be responsible for the annihilation of the value of forest habitats, in case of management actions aiming to “ameliorate” the viability or competitive ability of a representative or charismatic species in the formation.

Today the Mediterranean landscapes are profoundly different from the original ones. The vast impenetrable forests have mostly been replaced by fragmented patches, in turn more or less degraded, and more often by a sparse vegetation that fails to mask the outcropping rocks. Agro-silvo-pastoral system processes (i.e., the practice of combining forestry, grazing and farming) caused a progressive canopy opening and a simplification of the original closed forest (Correia, 1993). Dried up lands, picturesque but stripped cliffs, and beaches of Umbrella Pine or Stone Pine (*Pinus pinea*), are what Mediterranean Italy looks like today to those

Table 1 List of Mediterranean sclerophyllous forests from Annex I Habitat Directive.

Habitat Directive code	Description
9310	Aegean <i>Quercus brachyphylla</i> —Aegean oak woods
9330	<i>Quercus suber</i> —cork oak forests
9340	<i>Quercus ilex</i> and <i>Quercus rotundifolia</i> —holm oak forests
9350	<i>Quercus macrolepis</i> —valonia oak forests
9390	Scrub and low forest vegetation with <i>Quercus alnifolia</i> —Cyprus golden oak
93A0	Woodlands with <i>Quercus infectoria</i> —Lusitanian oak

Table 2 Area of Occupancy and trends in conservation status of Mediterranean evergreen *Quercus* woodland in Europe.

Country	Current area of habitat (km ²)	Recent trend in quantity (last 50 y)	Recent trend in quality (last 50 y)
Croatia	361	Stable	Stable
Cyprus	94	Increasing	Increasing
France	4000	Increasing	Stable
Greece	1837	Stable	Increasing
Italy	8050	Stable	Decreasing
Portugal	2930	Increasing	Unknown
Slovenia	0.5	Stable	Stable
Spain	31,855	Increasing	Stable

who access it along the most popular tourist routes. But those who like to search in more wild recesses, in the hills, in the coastal valleys, in the solitary lands, the vestiges of a more spontaneous vegetation, can give some idea of the ancient original forms of the forest cover that covered these shores, these first coastal heights. Relics of these evergreen forest can be found scattered only in small patches, especially in Tuscany and Roman Campagna (see Figs. 2 and 5), mainly on riverine slopes where the forest exploitation is naturally avoided. Structure and function of these relic woodlands must be taken into account for any restoration program in order to respect coherently the original pattern.

Conclusions and Conservation Recommendations

The evergreen forests of the Mediterranean do not seem to need further efforts in terms of the establishment of protected areas, as shown by the assessments conducted in various protectionist areas (see Red List and Article 17 of the Habitats Directive).

However, some management aspects can be addressed in order to improve the ecological function of Mediterranean evergreen forests. For example, it is necessary to ensure the maintenance of the tree cover and diversity (in structure and species composition) in order to protect the ecological niches of insects (e.g., several species of beetle for example the great capricorn beetle), nesting birds (i.e., woodpeckers, Eurasian wryneck and hoopoe) and bats. In general, the maintenance of the evergreen cover limits the effects of climate change, reducing the effect of drying up the soil while maintaining a good humidity level of its and consequently the ability to efficiently maintain active biogeochemical soil cycles (e.g., nitrogen cycle and of carbon). Specifically, in order to keep the aforementioned functions active, it is considered necessary to recommend management activities that limit the cutting of trees (see Fig. 6), grazing of domestic animals in the forest (see Fig. 7), and extraction activities especially for cork-oak woods (i.e., bark harvesting). Excessive cuts or poor silvicultural management can decrease forest diversity, density and biomass, destroying the necessary tree cover of the land and triggering species extinction and land erosive phenomena especially in years of poor atmospheric precipitation.

Abstract

Montane cloud forests (MCF) are a tropical mountainous biome that forms on the mountainous slopes oriented towards the sea under extremely wet climate in the temperate zone covered with clouds for the most part of the year. MCF receive water not only with rainfalls but also as mist. Most MCF are found mainly at the altitude between 500 and 2500 m above sea level (asl), but in places they extend to lower and higher elevations. Commonly these forests are divided into lower MCF belt, upland MCF belt and subalpine elfin forest. This biome is characterized by low stature and productivity compared with lowland rain forests due to excessive moisture, colder climate, acid nutrient-depleted soils and insufficient solar radiation. The physiognomy of MCF is characterized by numerous epiphytes that play an important role in moisture accumulation. Species diversity of MCF is lower than that of lowland tropical rain forests in absolute figures, but the biodiversity per area unit may be higher. Due to fragmentized distribution, the speciation in MCF is exceptionally high with increased levels of plant and animal endemism. The C stock of MCF is less than that of lowland tropical rainforests, but higher than of other mountainous forest types. The C stock in MCF is distributed evenly between the aboveground biomass and belowground stock (roots plus soil organic carbon). High biodiversity and endemism make MCF a priority area for conservation; currently this biome is endangered due to agriculture, settlements expansion and logging. Climatic change also may have a critical effect on MCF functioning and require special attention.

Introduction

The first studies of montane cloud forests (MCF) were in the 19th century, but a significant growth of interest in these ecosystems was observed in 1990s (Williams-Linera, 2015). Since then, several comprehensive reviews have appeared that provide an overview of this interesting and extremely vulnerable biome (Webster, 1995; Bubb et al., 2004; Bruijnzeel et al., 2010). MCF are tropical arboreal ecosystems with low plant stature, increased stem density and reduced nutrient cycling rates (Bruijnzeel and Veneklaas, 1998). MCF are affected by clouds continuously covering the mountains: the moisture comes to MCF both as rainfalls and mist. Since MCF represent a broad group of forest ecosystems varying with continent, altitude, and particular environment, it is difficult to give a brief definition of this biome. Hamilton et al. (1995) provided an extensive description of the physiognomic characteristics of MCF. The most characteristic features of the MCF are gnarled trunks, dense compact crowns, small, thick and hard leaves, and abundant epiphytes of various groups. Another interesting morphological feature is extra pigmentation due to the presence of anthocyanins and flavonoids (Flenley, 1995). Ohsawa (1995) indicated that in Asia in places it was difficult to distinguish MCF among other tropical rain forests, which were morphologically similar, and recommended using indicator species for forest classification.

Bruijnzeel et al. (2011) distinguish three MCF types commonly differing in hydrology and stature: tall lower montane cloud forest (LMCF); upper montane cloud forest (UMCF) of intermediate stature; and a group that combines stunted subalpine cloud forest (SACF) and “elfin” cloud forest (ECF). Though the absolute biodiversity of MCF is lower than of tropical rain forests, they have the highest species diversity per unit area. For example, in Mexico MCF includes 10%–12% of flora (2500–3000 vascular plant species) and 12% of terrestrial vertebrates found in the country (Toledo-Aceves et al., 2011; Sosa et al., 2016). The phenomenon may be ascribed to a high level of local endemism in MCF reaching 10%–24% of vascular plants, which can occur in ecologically isolated forests as small as 5–10 km² (Gentry, 1992). In Mexico the endemism of plants in MCF is estimated as high as 30% (Toledo-Aceves et al., 2011). The striking feature of MCF is abnormally quick speciation of plants that was estimated as taking 40 years (Webster, 1995), while for orchids speciation takes just 15 years (Gentry, 1992). The phenomenon can be mediated by genetic drift in small founder populations and thus the diversity in MCF does not come to any equilibrium and practically has no limits (Gentry, 1989).

MCF is one of the most endangered biomes in the worlds (Aldrich et al., 1997) due to the limited area, dependence on unique environmental conditions and extreme anthropogenic pressure.

Biogeography

Specific environments of cloudy mountains determine the physiognomy of MCF. Bruijnzeel and Veneklaas (1998) ascribe low stature of the MCF to a complex of environmental conditions such as low temperature, insufficient insolation due to the presence of permanent or continuous clouds, and excessive moisture. In general, the unique morphology and ecology of MCF is formed by the combination of permanent or prolonged inflow of moisture with cool but constant temperature and low insolation. These specific environments of MCF separate them from other forest biomes: MCF are colder than lowland tropical rainforests, wetter than mountainous deciduous or semideciduous forests, and do not have temperature fluctuations as temperate forests.

The most important environmental factor for MCF is rainfall together with humidity influenced by stable cloud condensation belts and the occurrence of frost that might limit the distribution of many tropical species (Hemp, 2006). The annual rainfall in MCF varies from 500 to 6000 mm (Bubb et al., 2004). Compared with other tropical forests, MCF receive 184 mm per year more rainfall on average and are 4.2°C cooler (Bruijnzeel et al., 2010). Also most researchers agree that cloud and mist occurrence is the most important microclimatic feature affecting the distribution and function of the plants in MCF, particularly for epiphytes (Oliveira et al., 2014). Bruijnzeel et al. (2011) studied the hydrology of MCF and showed that a significant part of water was received by this ecosystem as “cloud-water” interception. The amount of this source varied in a broad range from 22 to 1990 mm per year.

Low insolation is another feature related to prolonged cloud coverage of MCF: clouds reduce total insolation by about 30% (Bruijnzeel et al., 1993). Flenley (1995) noted a paradox of MCF: according to the general view trees grown in humid area with low insolation should be tall and have large, thin, and pale leaves. In contrast, most trees in MCF are stunted and have hard thick leaves. These features and elevated content of polyphenols in leaves of many plant species should be ascribed to extra UV-B light received by tropical high-altitude forests (Rozema et al., 1997). In this respect, the living forms of MCF plants reflect adaptation to negative effect of UV-B light; clouds protect MCF from harmful radiation but also reduce the income of energy required for photosynthesis.

Paleoecological reconstruction in northern Mesoamerica indicates that the present disjunct distributions of temperate and MCF woody genera in Mexico and Central America have resulted from climate change during the Neogene and Pleistocene, and that the colonization of tropical tree species and dynamics of cloud forests attributed solely to Pliocene processes has been obscured by Pleistocene climate changes (Sosa et al., 2016). During the Last Glacial Maximum, increased aridity strongly affected MCF causing their fragmentation, because some places remained fairly moist and served for MCF refugia (Ramírez-Barahona and Eguiarte, 2013). Repeated cycles of cloud forest contraction and expansion due to Pleistocene climatic cycling shaped genetic divergence in the MCF (Bruijnzeel et al., 2011).

The distribution of MCF biome has a good correspondence with the cloud circulation, and thus may be identified using remote sensing data (Nair et al., 2008). Also, Landsat allows direct identification of MCF and assessment of their area in particular sites (Cayuela et al., 2006). The majority of MCF is found at the altitudes between 500 and 2500 m, but strong fluctuations exist both for the lower and upper limit of this ecosystem. Small isolated mountains and especially islands are strongly affected by the Massenerhebung effect (“telescopic effect,” when altitudinal bioclimatic belts are found at lower elevations in small isolated mountains than in high mountainous systems) (Bruijnzeel et al., 1993; Flenley, 1995). Pouteau et al. (2018) reported the lower limit of MCF at 300 m asl on the small islands in Micronesia and Vanuatu, while on the big islands like Cuba and Hispaniola it was as high as 1600 m asl. In some specific cases, the occurrence of MCF at low elevation, like at 300–500 m asl in Angola, might be ascribed to paleoenvironments (Gioda et al., 1995).

The areal extent of MCF biome is estimated at 215,000 km² that is 6.6% of all montane tropical forests (Bruijnzeel et al., 2011) or 2.5% of the entire area of tropical forests. Bubb et al. (2004) report 381,166 km² of potential MCF worldwide with 25.3% located in the Americas, 15.0% in Africa and 59.7% in Asia. According to Scatena and Bruijnzeel (2010), about 43% of MCF is in Asia, 41% in North and South America, and 16% in Africa. Minor areas of MCF are found on many mountainous islands in Oceania (Meyer, 2010). The area of MCF may be also estimated on the basis of remotely sensed frequencies of cloud occurrence: fog-affected forest may occupy as much as 2,210,000 km² (Bruijnzeel et al., 2011) or 23% of the area of tropical forests (Toledo-Aceves et al., 2011), but it is not clear, if such forests would fit the central image of the MCF biome. MCF differ among continents: in Africa, they are generally drier than in Asia (Gioda et al., 1995; Bruijnzeel et al., 2010), while in the Americas these forests vary in humidity in a broad range.

It is important to note that most of the detailed studies on the diversity, ecology, and biomass in MCF have been from several well-studied localities. One of the most studied MCF sites is located in the Monteverde Cloud Forest Reserve, Costa Rica (Nadkarni and Longino, 1990; Nadkarni et al., 1995; Pounds et al., 1999; Köhler et al., 2007; Anchukaitis and Evans, 2010; Bruijnzeel et al., 2010; Tanner et al., 2016). In Mexico, multiple studies were conducted in Sierra Norte de Oaxaca (Bautista-Cruz and del Castillo, 2005; Álvarez-Arteaga et al., 2008, 2012, 2013, 2014; Meave et al., 2017) and the central part of Veracruz state (Pineda et al., 2005; Martínez et al., 2009; Williams-Linera and Vizcaíno-Bravo, 2016; Hernández-Pérez et al., 2018). Also, it is necessary to mention Luquillo Experimental Forest, Puerto Rico, where Brown et al. (1983) made their seminal detailed study.

Vegetative Community

General taxa—The biodiversity of tropical forests, including MCF, is still poorly known: Gentry (1992) estimated that each ecologically isolated patch of MCF in Andes had at least 20% of undescribed vegetative species. Meave et al. (2017) made an inventory of vascular plant species in Chinantla, Southern Mexico, and discovered 1021 species, 471 genera and 162 families; the authors estimate that the total number of species must be around 1650. Bruijnzeel et al. (2010) mention that in some sites the assessment of the diversity of vegetation is an almost impossible task. The number of plant species may go up to more than 1200 in Africa, 4000 in Asia and 5000 in Central America. It is notable that woody plants are also studied insufficiently in MCF, especially the trees of the diverse and poorly ordered families *Sapotaceae* and *Lauraceae* (Gentry, 1992).

Tree species—Brown et al. (1983) reported *Calycogonium squamulosum* as the dominant species in an elfin forest in Luquillo Experimental Forest, Puerto Rico among 23 arboreal plants found there; however, the major part of the canopy was constituted by other species, *Tabebuia rigida* and *Ocotea spathulata*. Nadkarni et al. (1995) studied a 4-ha plot in the Monteverde Cloud Forest Reserve, Costa Rica at the altitude 1480 m asl and with annual precipitation 2000–2500 mm. *Lauraceae* was the most abundant family of arboreal species and this was unusual for MCF. The authors ascribed the phenomena to the specific composition of bird population that could distribute the seeds of these trees. One hundred and eleven tree species were discovered; all but six constituted less than 2.5% of basal area, and one species *Ocotea tonduzii* constituted 23% of the total basal area of the trees. In other studies, the number of arboreal species varied in a broad range from 19 (Gunang Silam, Sabah) to 119 (Papua New Guinea) (Nadkarni et al., 1995). However, in some MCF, especially in small fragments and/or in relatively dry conditions, the diversity of arboreal species may be low. García-De La Cruz et al. (2013) found only 14 species of trees in the fragmented MCF of Veracruz, Mexico: *Quercus salicifolia*, *Liquidambar styraciflua*, *Quercus leiophylla* and *Alchornea latifolia* were the most abundant species. In dryer conditions in Sierra Gorda, Mexico, the number of tree species was even less and decreased with decreasing humidity of the habitats (Krasilnikov et al., 2016). Dominant tree species were *Liquidambar styraciflua*, *Dalbergia velutina*, *Trema micrantha*, *Carpinus caroliniana*, *Sambucus mexicana* and *Clethra mexicana*. A general observation on the composition of arboreal vegetation in MCF is that most of the sites have several dominant species, while other species are much less frequent, though the overall diversity may be high.

The diversity of plants generally decreases with elevation; also, it is broadly recognized that diversity is higher at mid-elevations between 500 and 2000 m than in subalpine forests (Bruijnzeel et al., 2010). Mean canopy and understory height also decreases with increasing elevation within the MCF belt (Gerold et al., 2008). In the Peruvian Andes, the dominant families of arboreal species at the elevation more than 3000 m asl were *Weinmannia*, *Clusiaceae*, *Canoniceae* and *Hesperomeles* (Girardin et al., 2010). *Canoniceae* and *Lauraceae* were abundant at 2720 m asl, *Clusiaceae*, *Clethraceae*, *Myrtaceae* and *Alzateaceae* dominated at 1855 and 2020 m asl. *Euphorbiaceae*, *Fabaceae* and *Lauraceae* were the dominant families at 1500 m asl, and *Moraceae*, *Fabaceae* and *Rubiceae* at 1000 m asl (Girardin et al., 2010). Though the abovementioned study did not establish clear boundaries between the lower and upper MCF, this example indicates that for the upper zone *Clusiaceae* is the family present in all the sites, while the lower MCF have *Fabaceae* family as a typical dominant.

Herbaceous and shrub species—Nontree species are often overlooked in the faunistic studies in tropical forests (Gentry, 1992). However, they may be indicative and even endemic for MCF. Ohsawa (1995) mentions that two fern genera, *Dicranopteris* and *Gleichenia*, are indicators of MCF in South-East Asia.

Epiphytes—also are characteristic of MCF and their presence is an indispensable attribute of this biome. In lower MCF, the majority of epiphytic vegetation is represented by flowering plants, and with increasing elevation the contribution of pteridophytic plant groups (vascular plants that disperse spores) increase (Bruijnzeel et al., 2010). The proportion of mosses and liverworts also increases with elevation, and they completely dominate in high-altitude elfin forests.

A small (300 ha) area of MCF within Brazilian Atlantic Forests hosted 224 species of vascular epiphytes (Furtado and Neto, 2018). These plants were distributed into 23 families of which *Orchidaceae* was the richest with 87 species. In Western Panama, 155 species of vascular epiphytes were discovered (Gómez-González et al., 2017). Hu et al. (2015) studied orchids at the Hainan Island, China and recorded 317 species and 102 genera of *Orchidaceae* for all the biomes of the island, however, without specifying how many of them were detected in MCF. They also mention that 158 species were epiphytic and associated with forests of high humidity. A recent study in Mexico showed that orchids in MCF prefer bigger trees with fissured bark (Hernández-Pérez et al., 2018).

Nonvascular epiphytes are also of importance in MCF: about 50% of mosses and 80% of liverworts reported for tropical Americas are restricted to MCF (Bruijnzeel et al., 2010). Brown et al. (1983) reported 18 species of mosses found on the trees in elfin forest in Luquillo Experimental Forest, Puerto Rico. The hydrological function of epiphytes is the capture of water directly from the mist and provision of a variety of microhabitats for fungi, invertebrates and amphibians; the decaying epiphytes form so-called “canopy humus” on the stems and branches of the trees. Both vascular and nonvascular epiphytes abundance depends on the canopy openness (Toivonen et al., 2017).

Fauna

Mammals—MCF are known for the high diversity of animals and especially for a high level of endemism. In Monteverde, Costa Rica the mammal list includes opossums, shrews, bats, monkeys, sloths, armadillos, anteaters, rabbits, porcupines, squirrels, rats, mice,

pacas, agoutis, large cats, coyote, gray fox, skunks, raccoons, tapir, peccaries and deer (Bruijnzeel et al., 2010). Perhaps the most well-known inhabitant of MCF in Africa is the mountain gorilla (*Gorilla beringei beringei*) (Doumenge et al., 1995). Bruijnzeel et al. (2010) estimated mean species richness for mammals in MCF to be 107.75 that was significantly higher than species richness in noncloud forests (74.65), while mean endemism in MCF was more than three times higher than in noncloud forests. These authors noted that the highest species diversity of mammals in MCF was observed in South-East Asia and in north-eastern Andes. The percentage of endemic mammals in the MCF of Andean region is estimated between 32% and 63% (Bubb et al., 2004).

Bats were studied intensively in MCF; over 40% of the animal species in the Monteverde cloud forest, Costa Rica mammals are bats (Bruijnzeel et al., 2010). In three sites in Veracruz, Mexico 10 species of bats were collected (Pineda et al., 2005). In Manu Biosphere Reserve, Peru the number of species of bats decreased with altitude within MCF from 30 to 10 (Willig and Presley, 2016). Similar pattern was detected for rodents: the number of species decreased from 18 to 10 with altitude (Willig and Presley, 2016).

Birds—Bird richness is also diverse in MCF with over 2500 species confined specifically to MCF, 1000 of them living in the South and North American MCF (Bruijnzeel et al., 2010). The same authors report highest diversity of birds in MCF within Atlantic forests in Brazil, the Guyana shield and the eastern Andes. Avian endemism is high: around 260 species of birds are endemic for MCF and other 315 species are typical for MCF plus similar habitats (Bubb et al., 2004). Together this makes almost a quarter of all bird species in the MCF having a restricted geographic range.

The distribution of birds depends on the altitude, for example, in Tilaran Mountains, Costa Rica the number of bird species decreased with altitude from 60 to 42 from the lower to the upper limit of MCF belt (Willig and Presley, 2016); in the mountainous rain forest below MCF the diversity of birds was higher. In Manu Biosphere Reserve, Peru the number of passerine species decreased with altitude within MCF from 220 to 120 (Willig and Presley, 2016). The diversity of birds also depends on the orientation of the slope. In Monteverde, Costa Rica on the drier Pacific slope there were 165 species of birds, while on the wetter Caribbean slope there were 315 species (Bruijnzeel et al., 2010).

Lloyd et al. (2012) studied avian richness in Kcosñipata Valley, Department of Cusco, southern Peru and detected about 50 species within the MCF. Compared with the tree-line and puna grassland vegetative communities, MCF had the highest bird diversity during both the dry and wet seasons; during the dry season the species richness of birds was slightly higher. Patterson et al. (1998) studied spatial patterns of distribution both of mammals and birds (901 bird species, 129 bat species, and 28 species of mice). The bat and bird faunas had a distinct limit at 1400 m asl between tropical low mountain and MCF ecosystems. For mice, the faunal transition took place nearer to 2000 m asl.

Herpetofauna—Bruijnzeel et al. (2010) showed that the mean species richness did not differ for amphibians in MCF and noncloud forests (24.69 vs. 23.50), but mean endemism was an order of magnitude higher for the MCF. They report the highest diversity of amphibians in the most humid part of Atlantic forests in Brazil, on the Guyana shield, in eastern escarpment of Andes, eastern Madagascar, Guinea and northern Kalimantan. In Mexico, endemism of amphibians and reptiles in MCF is estimates as 33% and 39%, respectively (Toledo-Aceves et al., 2011).

Invertebrates—this taxa has been insufficiently studied until now. More than a half of the species of beetles are site-specific in MCF (Bubb et al., 2004). The French Polynesia MCF host many rare species, for example aquatic insects such as endemic damselflies belonging to the genus *Bedfordia* and terrestrial arthropods such as spiders and weevils belonging to the genus *Rhyncogonus* (Meyer, 2010). Termites are common in lower MCF, while at higher elevations earthworms and beetles are more abundant (Bruijnzeel et al., 2010).

Nadkarni and Longino (1990) studied the invertebrates in the canopy and in soil litter and humus in the Monteverde Cloud Forest Reserve, Costa Rica and found the following taxa there: *Acarina* (mites), adult *Coleoptera* (beetles), insect larvae, *Formicidae* (ants), *Collembola* (springtails) and *Crustacea* (amphipods and isopods). The density of invertebrates was higher in the topsoil than in the canopy, the relative abundance of ants and mites was almost the same in these two strata, but the beetles and larvae were more abundant in the canopy, and the crustaceans dominated in soil. The number of species was not recorded in this study.

Soils

There is no specific soil group typical for all the MCF around the world: in each locality soil formation depends on the particular parent material, hydrology and composition of vegetation (Roman et al., 2010). The common features of the majority of soils under MCF are strong acidity, low content of nutrients and exchangeable bases and thick organic layer on the surface. Bruijnzeel and Veneklaas (1998) indicated that poor soil conditions result in a relatively strong development of root systems of the trees in MCF that probably leads to underdevelopment of aboveground parts of the arboreal plants.

Within the biome, soils commonly differ between the lower and upper MCF. Álvarez-Arteaga et al. (2008) showed that in the lower MCF in Sierra Norte de Oaxaca, Mexico the soils were *Folic Cambisols* (*Humic, Hyperdystric*) (IUSS Working Group WRB, 2014), brown acid soils rich in organic matter, while in the upper MCF belt the soils were *Folic Podzols* and *Folic Stagnosols*, soils with a bleached eluvial and/or saturated with perched water horizon under forest litter. In the Bolivian Andes, the main soil forming processes were podzolization and processes related to hydromorphism, such as gleying and peat accumulation (Schawe et al., 2007), and hydromorphism increases with increasing elevation. Álvarez-Arteaga et al. (2008) showed that the majority of the soils in the upper MCF belt and elfin forest had evidence of podzolization and gleying, in places a combination of these two processes, and accumulation of peat, including the formation of *Histosols* (organic soils) in the least drained localities. In lower MCF, the typical soils were *Cambisols* and *Ferralsols* (strongly weathered soils). In some relatively dry MCF, soils have evidences of clay

movement and have high base saturation in subsoil (Krasilnikov et al., 2016). The presence of specific substrates such as volcanic ash or limestone leads to the formation of peculiar soils that still reflect the MCF environments. Indicator tree species might differ depending on soil properties (Williams-Linera and Vizcaíno-Bravo, 2016): in Veracruz state, Mexico the composition of arboreal species was different on soils derived from volcanic material and from limestone. The indicators for shallow limestone-derived soils were *Cercis canadensis*, *Clusia guatemalensis*, *Garrya laurifolia*, *Ostrya virginiana* and *Quercus pinnatifida*, whereas for soils developed in volcanic material indicator species were *Carpinus tropicalis*, *Clethra macrophylla*, *Liquidambar styraciflua* and *Quercus xalapensis*.

Soil microbiology and mycology has not been studied much in MCF. Arias and Abarca (2014) detected 131 species of soil fungi mostly of the genera *Penicillium*, *Humicola*, *Fusarium*, *Trichoderma*, *Chaetomium* and *Paecilomyces* in central Veracruz state, Mexico that evidences the potential prospect of studying the fungi and microbial population of MCF soils.

Soils are commonly transformed if the forest is cut down and the land is used for agriculture. After reforestation, the soils are expected to return back to their initial state. Bautista-Cruz and del Castillo (2005) studied changes in soil properties in a chronosequence of recovering MCF in Sierra Norte de Oaxaca, Mexico after agricultural use. The soils under recovering forest vegetation during the first 100 years showed progressing growth of forest litter layer, loss of exchangeable bases and increase in exchangeable acidity returning back to the properties typical for MCF natural soils.

Biomass and C Stock Distribution

The biomass of MCF is less than that of lowland tropical rainforests, but higher than of other mountainous forests types (Keith et al., 2009). The biomass and total carbon stock of the ecosystem varies depending on the environmental conditions and elevation. However, a number of studies allow estimating the range of values; Álvarez-Arteaga et al. (2014) provided a review of the studies on the biomass and soil carbon stock in tropical mountainous forests. The biomass in MCF varied from 70 to 528 t ha⁻¹, soil carbon stock from 90 to 599 t ha⁻¹, and total C stock of the ecosystem from 162 to 946 t ha⁻¹. The data should be considered with caution, because the studies differed in methodologies.

Nadkarni et al. (2004) calculated the biomass in Monteverde Cloud Forest Reserve, Costa Rica to be 523.1 t ha⁻¹, with 33.1 t ha⁻¹ incorporated in “canopy organic matter,” that is, epiphytes and associated humus on the trunks. Dead organic matter or so-called “canopy humus” constitutes approximately half of the canopy organic matter (Nadkarni and Longino, 1990). The weight of epiphytic matter that includes living plants, canopy humus, litter and associated invertebrates and fungi varies from approximately 1000 to 44,000 kg ha⁻¹ (Gómez-González et al., 2017). Total biomass in two other MCF sites in the same reserve varied from 318.4 to 522.0 t ha⁻¹, where aboveground biomass was 159 to 457 t ha⁻¹ (Tanner et al., 2016). Köhler et al. (2007) also worked in the Monteverde Cloud Forest Reserve, Costa Rica and estimated the weight of bryophytes mat as 16,215 kg ha⁻¹ in an old-growth forest. The epiphytic vegetation on the trees was dominated by bryophytes with the weight 11,505 kg ha⁻¹ (71% of the entire canopy biomass). Canopy humus was 2095 kg ha⁻¹ (13%), whereas contributions by vascular plants were 2615 kg ha⁻¹ (16%), including 1228 kg ha⁻¹ of ferns and 131 kg ha⁻¹ of *Bromeliads*. It should be noted that the abovementioned study has been done in an extremely humid area with annual precipitation around 6000 mm; in drier conditions the bryophytes have lower relative abundance. On the forest floor in Luquillo Experimental Forest, the biomass of living plants was 3140 kg ha⁻¹, leaf litter and twigs 780 kg ha⁻¹ and roots 5770 kg ha⁻¹ (Brown et al., 1983). The mass of epiphytes and soil-like material on the stems consisted of living plants—2650 kg ha⁻¹, roots 1250 kg ha⁻¹ and “soil” 1120 g m⁻².

Girardin et al. (2010) studied an altitudinal sequence in the Kosñipata Valley, Peruvian Andes. The stem biomass carbon varied from 38.6 to 102.8 t ha⁻¹, belowground biomass from 14.8 to 19.3 t ha⁻¹, mineral soil C stock from 1.42 to 15.7 t ha⁻¹, and organic soil C stock from 8.45 to 68.8 t ha⁻¹. Stem and belowground biomass had a tendency to some decrease with elevation, but strongly varied, while soil carbon showed a regular decrease in mineral soil and increase in organic soil carbon with increasing altitude. Gerold et al. (2008) showed that soil C stock in a Bolivian MCF was the highest at the altitude 2000–2500 m asl (350–550 t ha⁻¹) and reduced to 200–300 t ha⁻¹ at higher elevations. Tanner et al. (2016) found that soil organic matter stock varied from 242.1 to 302.6 t ha⁻¹ in Monteverde Cloud Forest Reserve, Costa Rica. Álvarez-Arteaga et al. (2013) studied an altitudinal sequence in lower and higher MCF in Sierra Norte de Oaxaca, Mexico and found the total C stock to vary from 330.23 to 439.76 t ha⁻¹, with the highest values on the uppermost site (2500 m asl) and the lower limit (1500 m asl) and lower values between these points. Soil C stock decreased with elevation from 222.5 to 158.2 t ha⁻¹, and constituted 38%–59% of the total C stock of the ecosystem. In all the sites except of the most elevated the major part of soil C was stores in organic layers (Álvarez-Arteaga et al., 2012).

The biomass of MCF is inferior to the lowland rainforests due to lower intensity of physiological processes under unfavorable environments in the cloud belt. The mean photosynthesis rate of MCF trees is 7.2 $\mu\text{mol m}^{-2} \text{s}^{-1}$ that is lower than that in lowland tropical forests (10 $\mu\text{mol m}^{-2} \text{s}^{-1}$) (Gotsch et al., 2016). As a result net primary productivity (NPP) assessment in the Kosñipata Valley, Peruvian Andes resulted in a range from 4.11 to 7.07 t C ha⁻¹ year⁻¹ (Girardin et al., 2010) that was slightly lower than the range reported for MCF by Gotsch et al. (2016) from 7 to 12 t C ha⁻¹ year⁻¹. NPP decreases with elevation and is especially low in elfin and subalpine cloud forests. In “dwarf forest” after clearcutting the biomass increased slowly: in the first 2 years the accumulation was 95 g m⁻² per year and then increased to 212 g m⁻² per year (Brown et al., 1983).

MCF Under Anthropogenic Pressure

Anthropogenic pressure to MCF is extreme worldwide. In Africa, agricultural fields are found at altitudes up to 2400 m asl, and pastures up to 3000 m asl, and in South America, fields go up to 3700 m asl and pastures to 4000 m asl (Doumenge et al., 1995). Conversion of MCF to coffee or tea plantations or to pastures is widespread all over the world (Martínez et al., 2009). Toledo-Aceves et al. (2011) name cattle grazing, illegal logging, land tenure conflicts, agriculture, roads construction, inappropriate use of fire, and extraction of stone materials among the main threats to MCF in Mexico. In Veracruz, Mexico the area of MCF decreased to almost half their original surface during the period between 1973 and 2003 (Martínez et al., 2009). Sarmiento and Frolich (2002) argue that the distribution of MCF in Andes is geographically limited by human activities such as grazing and potato cultivation. Bubb et al. (2004) report that the area of mountainous forests, some of which are cloud forests, in the eastern part of Madagascar declined from 8 million ha in 1900 to 7 million ha in 1950, and to less than 1 million ha by 1995. Urban sprawl is becoming a growing challenge for MCF, especially informal settlements represent a menace for this fragile ecosystem in the developing countries (Benítez et al., 2012).

Land use change results in the loss of biodiversity. The MCF in Veracruz, Mexico had 260 plant species, while coffee plantations under natural vegetation had 237 and grassland only 183 species (Martínez et al., 2009). Shannon's diversity index decreased in the sequence MCF-coffee plantation-grassland in the sequence 5.576-5.464-5.193 for all plant species and 4.654-3.850-3.258 for woody species (Martínez et al., 2009). The species richness of frogs was one-fifth less in coffee plantations than in forest fragments, and only one-third of the frog species occurred in both forest fragments and coffee plantations. The number of beetle species and their abundance was significantly greater in coffee plantations than in the forest fragments, whereas species richness and species composition of bats were virtually the same in both habitats (Pineda et al., 2005). Though recent studies (Brüning et al., 2018) show that small-scale agriculture can even promote biodiversity of amphibian in MCF, the reduction of the area of MCF results in fragmentation of the forest that may lead to the negative effect on the animals inhabiting the remnants of the forest (Cayuela et al., 2006). It should be also stressed that besides biodiversity the loss of MCF also affects other ecosystem services, especially water quality (Martínez et al., 2009).

MCF Under Climatic Change

Modeling climatic change scenario of doubled CO₂ concentration showed that the relative humidity surface in the mountains might be shifted upwards several hundreds of meters (Still et al., 1999). Warming also can lead to the reduction in the number of days with mist (Pounds et al., 1999); in combination with increased evapotranspiration with escalated temperature the climatic change would lead to the reduction and in places even extinction of MCFs (Foster, 2001). Modeling of climatic change using general circulation model (GCM) until 2050 suggests a strong effect on the hydrology and ecology of MCF, although different models provide contradictory results (Bruijnzeel et al., 2011). Poor quality of prediction might be explained by coarse resolution of GSMs (1°) that is insufficient to reflect complex topography typical for MCF habitats (Hu and Riveros-Iregui, 2016). Loope and Giambelluca (1998) shared concern of possible climatic change effect on the extremely fragile MCF ecosystems on Hawaii Islands. However, on small islands the effect of the increased temperature may be minor: recent estimation for tropical islands was 4.4 m shift of relative humidity surface per 1°C increase in mean annual temperature (Pouteau et al., 2018). Hu and Riveros-Iregui (2016) mention that most of the studies focus on the change in the environments and not the reaction of MCF trees on reduced moisture availability. The authors propose a new approach based on coupled $\delta^{18}\text{O}_{\text{cellulose}}$ and $\delta^{13}\text{C}_{\text{cellulose}}$ that has the potential for understanding physiological effect of reduced cloud water interception due to climate drying. Benzing (1998) showed that epiphytes are the most sensitive species, which might be used as early indicators of the response of MCF to the climatic change. The reaction of epiphytes in MCF to the El Niño caused droughts was stronger and the recovery slower than in other drier habitats that shows their high vulnerability to drought stress (Gotsch et al., 2018). Rapp and Silman (2014) experimentally showed that epiphytes strongly differed in their response to drying, the species from the upper limit of MCF distribution being more sensitive than the species from the lower MCF.

Twenty of 50 species of frogs and toads disappeared from 1976 to 1999 in Monteverde Cloud Forest Reserve, Costa Rica due to the decreased frequency of mists that was ascribed to the increase in air temperatures that followed a step-like warming of tropical oceans (Pounds et al., 1999). Anchukaitis and Evans (2010) used stable oxygen isotope measurements from trees without annual rings to reconstruct a century of hydroclimatology in the same reserve and found no evident trend related to global warming. However, they found significant oscillations related to El Niño events, and ascribed the extinction of the Monteverde golden toad to a dry period associated with El Niño. It should be mentioned that the climatic change effect may vary in the MCF in different parts of the world, and further research is required for understanding the threats of climatic change for MCF biodiversity.

The MCF ecosystems are vulnerable and difficult to restore, but their reforestation is still possible (Bruijnzeel et al., 2010). After abandonment of the agricultural fields in the MCF zone natural vegetation recovers, but the process is long, and after 30 years of secondary forest development the epiphytes did not reach the abundance and biomass typical for old-growth MCF (Köhler et al., 2007). The restoration of MCF is a complex task that should include best available science, native species production in nurseries, monitoring, training for local stakeholders, knowledge dissemination and land protection (Ramírez-Soto et al., 2018). The pressure on MCF should be minimized, and systematic policies should be developed to conserve the unique MCF biome (Peh et al., 2011).

Abstract

Motivations for establishing forest protected areas have expanded over the years from a focus on landscape and species towards social needs, biodiversity conservation, and maintenance of ecosystem services. Protected areas are defined and their range of management approaches and governance types described. Other similar area-based approaches that are not full protected areas are also described. Estimates of forest protected areas range from 13.5% to 20.1% of remaining forest cover globally. Some of the social issues surrounding forest protection are discussed and management effectiveness described in terms of both forest cover and the survival of biodiversity in the face of land clearance, poaching of wildlife and timber, and pervasive threats such as climate change. The future of forest conservation is discussed briefly, including new threats from anti-environmental populist politicians and the potential for steps to control climate change providing a unifying factor for forest protected areas.

Introduction

Areas of forest have been set aside from exploitation for thousands of years. Motivations have varied: many societies protected particular sacred groves for religious reasons (Porteus, 1928). In Europe, forests were maintained and guarded as hunting grounds for the aristocracy (Schama, 1995). In countries such as Japan (Kumazaki et al., 1991) and Switzerland (Dapples et al., 2002) conserved forests on steep slopes have reduced erosion and avalanches for hundreds of years. And in the Middle East the *hima* system protected dryland forests for their ecosystem services (Bagader et al., 1994).

The contemporary model of a protected area came much later. The first handful of national parks were established in the United States, Australia, and India at the end of the 19th century and numbers increased gradually in the first half of the 20th century, before expanding rapidly after 1980 (Gissibli et al., 2012). Most modern protected areas have been set up in the last 30 years; it is hard to think of another conscious, large-scale change of land use that occurred so fast.

The reasons for establishing protected areas have changed over time; or rather additional reasons have been added to older motives (Watson et al., 2014). The earliest national parks were identified largely for their landscape values, as in the Blue Mountains National Park outside Sydney, Australia, or to protect a single species as in Kaziranga National Park, Assam, India, conserving the Asian rhinoceros (*Rhinoceros unicornis*) (Mathur et al., 2007). Next, recreation became a driving force as in the Peak District, the first British national park, created largely to provide city dwellers with access to the countryside (MacEwan and MacEwan, 1982).

Rapid rate of forest loss, particularly in the tropics, created a wave of concern from the 1970s onwards. Between 1980 and 1990, the Food and Agriculture Organization of the United Nations (FAO) estimated annual losses in the developing world of over 150,000 km² (FAO, 1997); figures that other analysts felt were too low (Matthews et al., 2000). Countries like the Philippines and Cote d'Ivoire lost virtually all natural forests in a generation. While forest area in the temperate and boreal regions was generally increasing after a historical low, natural forests were frequently replaced by severely degraded forests and pulpwood plantations, with forests untouched for 200 years averaging less than 1% of total forest area in most European countries (UNECE and FAO, 2000) and rapid loss of old-growth forests in North America causing an intense debate (DellaSala, 2011). These changes, coupled with a rapid rate of species loss (Myers, 1979) and new understanding about biodiversity, created an impetus for setting aside native forest throughout the world. Protected areas were designated explicitly to protect forest ecosystems and the global network grew rapidly (Schmidt et al., 2009). More recently, forest protection has paid increasing attention to maintaining ecosystem services, including the storage and sequestration of carbon in response to climate change.

What is a Forest Protected Area? Definitions and Varieties

"Protected area" is a problematical concept, and people's understanding of the term differs around the world and between stakeholder groups. National parks, nature reserves, wilderness areas and a wide variety of community or indigenous conservation

approaches all fall under the general term. The UN Convention on Biological Diversity (CBD) defines a protected area as: “a geographically defined area which is designated or regulated and managed to achieve specific conservation objectives.” The International Union for Conservation of Nature (IUCN) has a different definition, which the CBD recognizes as being equivalent: “A clearly defined geographical space, recognized, dedicated and managed, through legal or other effective means, to achieve the long-term conservation of nature with associated ecosystem services and cultural values” (Dudley, 2008).

Some of the words are particularly important. “Conservation” refers to the in situ maintenance of ecosystems and natural and semi-natural habitats and of viable populations of species in their natural surroundings. “Dedicated” implies binding commitment to long term conservation through international conventions, national and local law, customary law, NGO covenants, private trusts and company policies. “Managed” assumes conscious steps to conserve the protected area’s values. “Legal or other effective means” implies that protected areas must be gazetted (established legally) under statutory civil law, recognized through an international convention or agreement, or managed through means such as traditional community rules or the policies of established nongovernmental organizations. “To achieve” assumes effectiveness (Dudley, 2008).

These definitions are guidelines: the details of what “counts” as a protected area, and is listed in the United Nation’s World Database on Protected Areas (WDPA), is determined by national policy and legislation. Protected areas are not all managed in the same way, and can vary between areas entirely without human presence to cultural landscapes that include settled human communities. Both IUCN and the CBD recognize six management categories, as summarized in Table 1, as long as the area also meets the definition of a protected area.

Not all protected areas are under the control of the state and other stakeholders sometimes make the management decisions. IUCN recognizes a range of governance types (Borrini-Feyerabend et al., 2013), as in Table 2.

Forest protected areas are therefore variable in both management aims and management authority, albeit under a single definition. Deciding what falls inside or outside the definition has created long debates, particularly in Europe (Dudley and Phillips, 2006). The situation is further complicated by the existence of several other management approaches that, whilst not strictly protected areas according to the IUCN definition, play a similar role in area-based conservation. Many countries, particularly in Africa and Asia, have a system of “forest reserves,” initially established to maintain timber stocks (Burgess et al., 2007). While some have disappeared or become timber plantations, others have high conservation value and can be regarded as part of the conservation estate. Indeed, a proportion has been converted into protected areas, for example, in Uganda (Howard et al., 2000).

A potentially much larger, but more complicated category, agreed by signatory states of the CBD in November 2018, is Other Effective Area-Based Conservation Measures (OECMs), commonly known as Conservation Areas. When the CBD agreed a target for global protected areas in Sendai, Japan in 2010, the text referred to “protected areas and other effective area based conservation measures” without defining the latter (Woodley et al., 2012). It took eight years of deliberation and a task force from IUCN to agree a definition: “a geographically defined area other than a protected area, which is governed and managed in ways that achieve positive and sustained long-term outcomes for the in situ conservation of biodiversity, with associated ecosystem functions and services and where applicable, cultural, spiritual, socio-economic, and other locally relevant values” (CBD, 2018). Forests recognized as OECMs will likely be increasingly important in area-based conservation in the future, although they are by definition not protected areas.

Table 1 IUCN and the CBD recognize several different management categories

Management category	Details
Ia	Strictly protected areas to protect biodiversity and also possibly geological/geomorphological features, where human visitation and use are strictly controlled and limited. Such areas can serve as reference areas for scientific research. Example: Maltion luonnonpuisto, Finland
Ib	Usually large unmodified or slightly modified areas, retaining their natural character and influence, without permanent or significant human habitation, which are protected and managed to preserve natural condition. Example: Misty Fjords National Monument in Alaska, United States, part of the Tongass National Forest
II	Large natural or near-natural areas protecting large-scale ecological processes, along with characteristic species and ecosystems, while providing environmentally and culturally compatible spiritual, scientific, educational and recreational opportunities. Example: Volcanoes National Park, Rwanda
III	Generally quite small areas to protect a specific natural monument, which can be a landform, sea mount, submarine cavern, geological feature or even a living feature like an ancient grove. Example: Coal River Springs in Canada
IV	Areas protecting particular species or habitats, where management reflects this priority. Many category IV protected areas will need regular, active interventions to meet the needs of particular species or habitats, but this is not a requirement of the category. Example: Otun Quimbaya Fauna and Flora Sanctuary, Colombia
V	Areas where the interaction of people and nature over time has produced a distinct character with significant ecological, biological, cultural and scenic value: and where safeguarding the integrity of this interaction is vital to sustaining the area and its values. Example: native woodland in Snowdonia National Park, Wales United Kingdom
VI	Areas conserving ecosystems and habitats, with associated cultural values and traditional natural resource management. They are generally large, mostly in natural condition, with a proportion under low-level nonindustrial natural resources use compatible with conservation. Example: Peru Mountain Forest Reserve in Jamaica

Table 2 Governance types: IUCN and the CBD recognize four governance types of protected areas

A	Governance by governments: a government body (a Ministry, Park Agency or sometimes an NGO contracted by government) manages the protected area and determines its management aims and objectives. Example: Bwindi Impenetrable Forest National Park in Uganda
B	Shared governance: complex institutional mechanisms and processes share management authority and responsibility amongst a plurality of (formally and informally) entitled governmental and nongovernmental actors. Example: 13 national parks in Canada are jointly managed by the government and First Nation groups
C	Private governance: protected areas under individual, cooperative, NGO or corporate control and/or ownership set up and managed under not-for-profit or for-profit schemes. Example: the forest reserves owned and managed by the Woodland Trust in the United Kingdom
D	Indigenous or community governance: Includes two subsets: (1) indigenous peoples' areas and territories established and run by indigenous peoples. Example: Indigenous Protected Areas in Australia; (2) community conserved areas established and run by local communities. Example: some community conservancies in Namibia

Borrini-Feyerabend, G., Dudley, N., Jaeger, T., Lassen, B., Pathak Broome, N., et al. (2013). *Governance of protected areas: From understanding to action*. Best Practice Protected Area Guidelines number 20. Gland: IUCN.

Governments sometimes prioritize other forests for soil protection, erosion and landslide control, as water sources and for carbon storage. Some may be managed in ways that are indistinguishable from forest protected areas and will likely eventually be recognized as OECMs or as protected areas.

How Much Forest Protected Area Exists?

The global coverage of protected areas has expanded rapidly, with rates of designation moving much more quickly than anyone expected. When IUCN first suggested that 10% of the world's land surface should be in protected areas the target was viewed as little more than a fantasy (IUCN, 1992). But by 2010, signatory countries of the CBD agreed to a target of 17% of land surface and 10% of the oceans (CBD, 2010) and there is a growing movement amongst ecologists that this remains way too low (e.g., Half-Earth: Noss et al., 2012; Wilson, 2016).

As of June 2018, there were 238,563 designated protected areas on the World Database on Protected Areas (WDPA). Those on land cover over 20 million km², 14.9% of the earth's land surface (UNEP WCMC, IUCN and NGS, 2018). Precise figures change; new areas are designated, existing areas are finally reported, and some areas lose their protection status, a phenomenon known as Protected Area Downgrading, Downsizing and Degazettement (PADDD) (Mascia and Pailler, 2010).

Working out the proportion of terrestrial protected areas that are also forest protected areas is more complicated. Governments do not report ecosystem types to the WDPA and even if they did many protected areas contain a mixture of ecosystems. There is a continuing debate about the definition of forest (e.g., Putz and Redford, 2009), particularly in sparsely wooded areas like tundra and drylands. Nonetheless, estimates exist. In 2014, the UNEP World Conservation Monitoring Centre estimated that 7,848,782 km² of forest was in protected areas, 20.1% of the global forest area, meaning that roughly a fifth of the world's forest is now under some kind of protection (Juffe-Bignoli et al., 2014), see Table 3.

This is larger than an estimate in the 2015 *Global Forest Resources Assessment* from FAO, which proposed a global figure of 6,510,000 km² forests in protected areas, although confusingly in the same publication FAO reported forest managed primarily for biodiversity conservation at only 5,240,000 km² (Food and Agriculture Organization of the United Nations (FAO), 2015), or 13% of total forests. This smaller figure accorded with a 2009 study by Schmidt et al., who estimated protected forest area cover at 13.5%; however, many more forest protected areas have been established since.
